Amortized

• Recall our plain-old stack implemented as an array that doubles its size if it runs out of room
  – How can we claim push is $O(1)$ time if resizing is $O(n)$ time?
  – We can't, but we can claim it's an $O(1)$ amortized operation

• What does amortized mean?
• When are amortized bounds good enough?
• How can we prove an amortized bound?

Will just do two simple examples
  – The text has more complicated examples and proof techniques
  – The idea of how amortized describes average cost is essential

Amortized Complexity

If a sequence of $M$ operations takes $O(M \cdot f(n))$ time,
we say the amortized runtime is $O(f(n))$

• The worst case time per operation can be larger than $f(n)$
  – For example, maybe $f(n) = 1$, but the worst-case is $n$

• But the worst-case for any sequence of $M$ operations is $O(M \cdot f(n))$

Amortized guarantee ensures the average time per operation for any sequence is $O(f(n))$

Amortized bound: worst-case guarantee over sequences of operations
  – Example: If any $n$ operations take $O(n)$, then amortized $O(1)$
  – Example: If any $n$ operations take $O(n^3)$, then amortized $O(n^2)$

Example #1: Resizing stack

From lecture 1: A stack implemented with an array where we double the size of the array if it becomes full

Claim: Any sequence of push/pop/isEmpty is amortized $O(1)$

Need to show any sequence of $M$ operations takes time $O(M)$
  – Recall the non-resizing work is $O(M)$ (i.e., $M \cdot O(1)$)
  – The resizing work is proportional to the total number of element copies we do for the resizing
  – So it suffices to show that:
    After $M$ operations, we have done $< 2M$ total element copies
    (So number of copies per operation is bounded by a constant)
Amount of copying

After $M$ operations, we have done < $2M$ total element copies.

Let $n$ be the size of the array after $M$ operations.

- Then we've done a total of:
  \[ \frac{n}{2} + \frac{n}{4} + \frac{n}{8} + \ldots \text{INITIAL\_SIZE} \leq n \]
  element copies
- Since we must have done at least enough push operations to cause resizing up to size $n$:
  \[ M \geq \frac{n}{2} \]
- So
  \[ 2M \geq n \]

Other approaches

- If array grows by a constant amount (say 1000), operations are not amortized $O(1)$
  - After $O(M)$ operations, you may have done $\Theta(M^2)$ copies

- If array shrinks when 1/2 empty, operations are not amortized $O(1)$
  - Terrible case: pop once and shrink, push once and grow, pop once and shrink, ...

- If array shrinks when 3/4 empty, it is amortized $O(1)$
  - Proof is more complicated, but basic idea remains: by the time an expensive operation occurs, many cheap ones occurred.

Example #2: Queue with two stacks

A clever and simple queue implementation using only stacks.

```java
class Queue<E> {
    Stack<E> in = new Stack<E>();
    Stack<E> out = new Stack<E>();
    void enqueue(E x){ in.push(x); }
    E dequeue(){
        if(out.isEmpty()) {
            while(!in.isEmpty()) {
                out.push(in.pop());
            }
        }
        return out.pop();
    }
}
```

Example #2: Queue with two stacks

A clever and simple queue implementation using only stacks.

```java
class Queue<E> {
    Stack<E> in = new Stack<E>();
    Stack<E> out = new Stack<E>();
    void enqueue(E x){ in.push(x); }
    E dequeue(){
        if(out.isEmpty()) {
            while(!in.isEmpty()) {
                out.push(in.pop());
            }
        }
        return out.pop();
    }
}
```
Example #2: Queue with two stacks
A clever and simple queue implementation using only stacks

```java
class Queue<E> {
    Stack<E> in = new Stack<E>();
    Stack<E> out = new Stack<E>();
    void enqueue(E x) { in.push(x); }
    E dequeue() {
        if(out.isEmpty()) {
            while(!in.isEmpty()) {
                out.push(in.pop());
            }
        }
        return out.pop();
    }
}
```

displays stack diagrams

Correctness and usefulness

- If `x` is enqueued before `y`, then `x` will be popped from `in` later than `y` and therefore popped from `out` sooner than `y`
  - So it's a queue

- Example:
  - Wouldn’t it be nice to have a queue of t-shirts to wear instead of a stack (like in your dresser)?
  - So have two stacks
    - `in`: stack of t-shirts go after you wash them
    - `out`: stack of t-shirts to wear
    - If `out` is empty, reverse `in` into `out`
Analysis

• \texttt{deque}ue is not \(O(1)\) worst-case because \texttt{out} might be empty and \texttt{in} may have lots of items

• But if the stack operations are (amortized) \(O(1)\), then any sequence of queue operations is amortized \(O(1)\)
  
  – The total amount of work done per element is 1 \texttt{push} onto \texttt{in}, 1 \texttt{pop} off of \texttt{in}, 1 \texttt{push} onto \texttt{out}, 1 \texttt{pop} off of \texttt{out}

  – When you reverse \(n\) elements, there were \(n\) earlier \(O(1)\) \texttt{enqueue} operations to average with

Amortized useful?

• When the average per operation is all we care about (i.e., sum over all operations), amortized is perfectly fine
  
  – This is the usual situation

• If we need every operation to finish quickly (e.g., in a concurrent setting), amortized bounds are too weak

• While amortized analysis is about averages, we are averaging cost-per-operation on worst-case input
  
  – Contrast: Average-case analysis is about averages across possible inputs. Example: if all initial permutations of an array are equally likely, then quicksort is \(O(n \log n)\) on average even though on some inputs it is \(O(n^2)\)

Not always so simple

• Proofs for amortized bounds can be much more complicated

• Example: Splay trees are dictionaries with amortized \(O(\log n)\) operations
  
  – No extra height field like AVL trees
  
  See Chapter 4.5

• For more complicated examples, the proofs need much more sophisticated invariants and “potential functions” to describe how earlier cheap operations build up “energy” or “money” to “pay for” later expensive operations
  
  – See Chapter 11

• But complicated \textit{proofs} have nothing to do with the code!
