

CSE332: Data Abstractions

Lecture 4: Priority Queues

Dan Grossman
Spring 2012

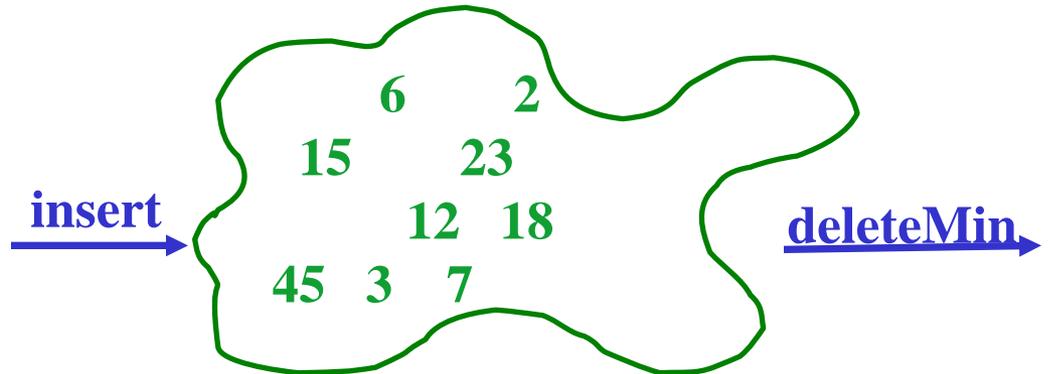

A new ADT: Priority Queue

- Textbook Chapter 6
 - Will go back to binary search trees and hash tables
 - Nice to see a new and surprising data structure first
- A **priority queue** holds *compare-able data*
 - Unlike stacks and queues need to *compare items*
 - Given x and y , is x less than, equal to, or greater than y
 - Meaning of the ordering can depend on your data
 - Many data structures require this: dictionaries, sorting
 - Integers are comparable, so will use them in examples
 - But the priority queue ADT is much more general
 - Typically two fields, the *priority* and the *data*

Priorities

- Each item has a “priority”
 - The *lesser* item is the one with the *greater* priority
 - So “priority 1” is more important than “priority 4”
 - (Just a convention)

- Operations:
 - `insert`
 - `deleteMin`
 - `is_empty`

- Key property: `deleteMin` *returns* and *deletes* the item with greatest priority (lowest priority value)
 - Can resolve ties arbitrarily

Example

```
insert x1 with priority 5
insert x2 with priority 3
insert x3 with priority 4
a = deleteMin // x2
b = deleteMin // x3
insert x4 with priority 2
insert x5 with priority 6
c = deleteMin // x4
d = deleteMin // x1
```

- Analogy: **insert** is like **enqueue**, **deleteMin** is like **dequeue**
 - But the whole point is to use priorities instead of FIFO

Applications

Like all good ADTs, the priority queue arises often

- Sometimes blatant, sometimes less obvious
- Run multiple programs in the operating system
 - “critical” before “interactive” before “compute-intensive”
 - Maybe let users set priority level
- Treat hospital patients in order of severity (or triage)
- Select print jobs in order of decreasing length?
- Forward network packets in order of urgency
- Select most frequent symbols for data compression (cf. CSE143)
- Sort (first **insert** all, then repeatedly **deleteMin**)
 - Much like Project 1 uses a stack to implement reverse

More applications

- “Greedy” algorithms
 - Will see an example when we study graphs in a few weeks
- Discrete event simulation (system simulation, virtual worlds, ...)
 - Each event e happens at some time t , updating system state and generating new events e_1, \dots, e_n at times $t+t_1, \dots, t+t_n$
 - Naïve approach: advance “clock” by 1 unit at a time and process any events that happen then
 - Better:
 - *Pending events* in a priority queue (priority = event time)
 - Repeatedly: **deleteMin** and then **insert** new events
 - Effectively “set clock ahead to next event”

Finding a good data structure

- Will show an efficient, non-obvious data structure
 - But first let's analyze some “obvious” ideas for n data items
 - All times worst-case; assume arrays “have room”

<i>data</i>	<i>insert algorithm / time</i>	<i>deleteMin algorithm / time</i>
unsorted array		
unsorted linked list		
sorted circular array		
sorted linked list		
binary search tree		

Need a good data structure!

- Will show an efficient, non-obvious data structure for this ADT
 - But first let's analyze some “obvious” ideas for n data items
 - All times worst-case; assume arrays “have room”

<i>data</i>	<i>insert algorithm / time</i>		<i>deleteMin algorithm / time</i>	
unsorted array	add at end	$O(1)$	search	$O(n)$
unsorted linked list	add at front	$O(1)$	search	$O(n)$
sorted circular array	search / shift	$O(n)$	move front	$O(1)$
sorted linked list	put in right place	$O(n)$	remove at front	$O(1)$
binary search tree	put in right place	$O(n)$	leftmost	$O(n)$

More on possibilities

- *If priorities are random, binary search tree will likely do better*
 - $O(\log n)$ **insert** and $O(\log n)$ **deleteMin** on *average*
- One more idea: if priorities are $0, 1, \dots, k$ can use array of lists
 - **insert**: add to front of list at `arr[priority]`, $O(1)$
 - **deleteMin**: remove from lowest non-empty list $O(k)$
- We are about to see a data structure called a “binary heap”
 - $O(\log n)$ **insert** and $O(\log n)$ **deleteMin** *worst-case*
 - Possible because we don’t support unneeded operations; no need to maintain a full sort
 - Very good constant factors
 - *If items arrive in random order, then **insert** is $O(1)$ on average*

Tree terms (review?)

The binary heap data structure implementing the priority queue ADT will be a *tree*, so worth establishing some terminology

root(tree)

leaves(tree)

children(node)

parent(node)

siblings(node)

ancestors(node)

descendents(node)

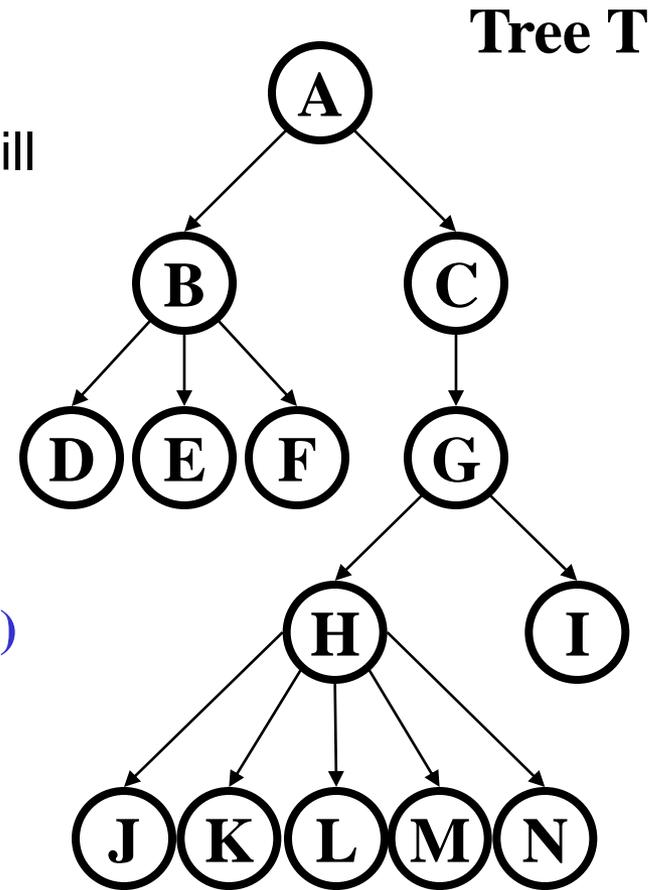

subtree(node)

depth(node)

height(tree)

degree(node)

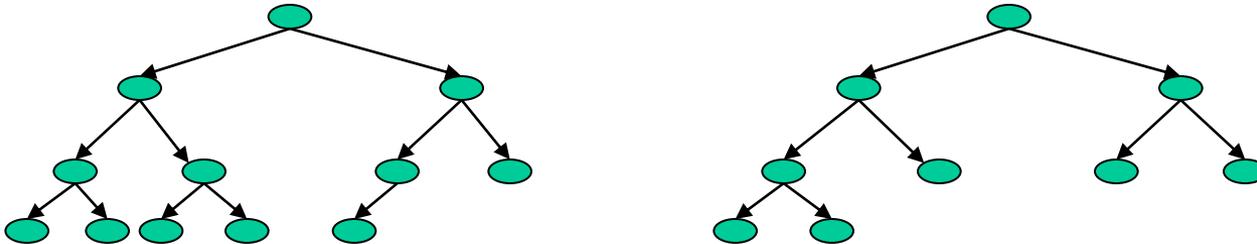

branching factor(tree)

Kinds of trees

Certain terms define trees with specific structure

- **Binary tree**: Each node has at most 2 children (branching factor 2)
- **n -ary tree**: Each node has at most n children (branching factor n)
- **Perfect tree**: Each row completely full
- **Complete tree**: Each row completely full except maybe the bottom row, which is filled from left to right

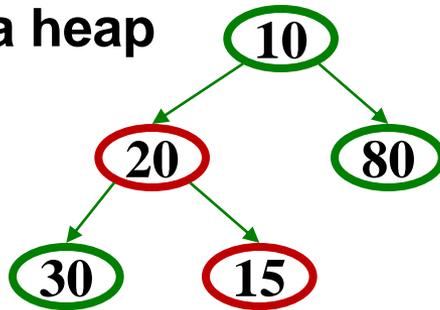

What is the height of a **perfect** tree with n nodes? A **complete** tree?

Our data structure

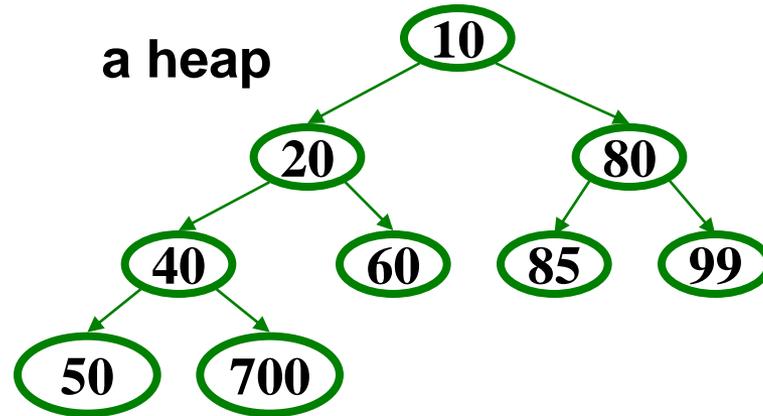

Finally, then, a *binary min-heap* (or just *binary heap* or just *heap*) is:

- **Structure property:** A complete binary tree
- **Heap property:** The priority of every (non-root) node is greater than the priority of its parent
 - **Not** a binary search tree

not a heap

a heap

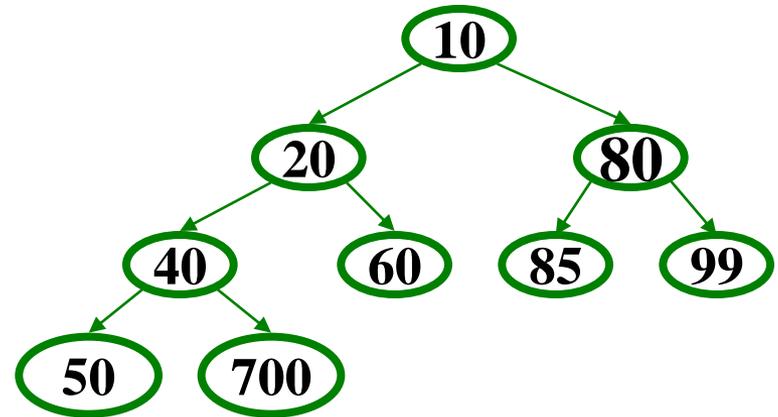

So:

- Where is the highest-priority item?
- What is the height of a heap with n items?

Operations: basic idea

- **findMin**: return `root.data`
- **deleteMin**:
 1. `answer = root.data`
 2. Move right-most node in last row to root to restore structure property
 3. “Percolate down” to restore heap property
- **insert**:
 1. Put new node in next position on bottom row to restore structure property
 2. “Percolate up” to restore heap property

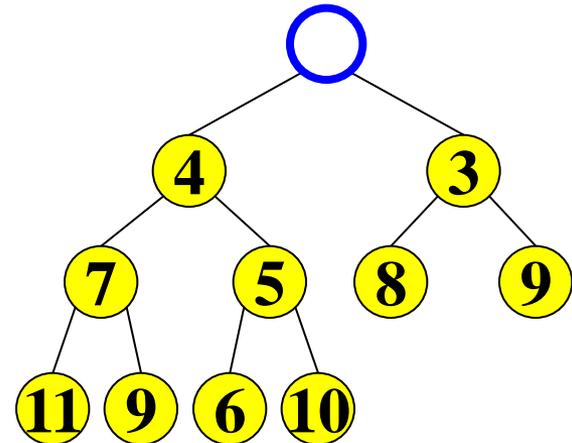

Overall strategy:

- *Preserve structure property*
- *Break and restore heap property*

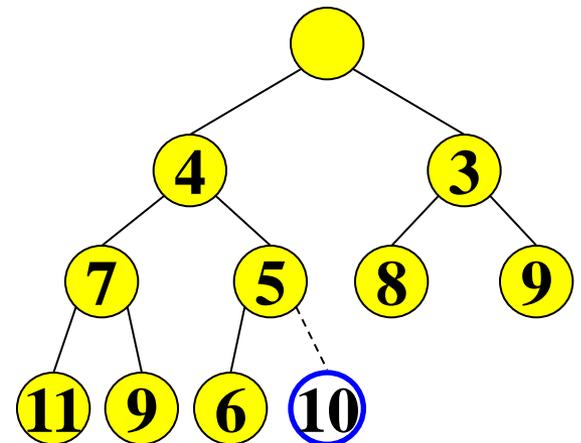

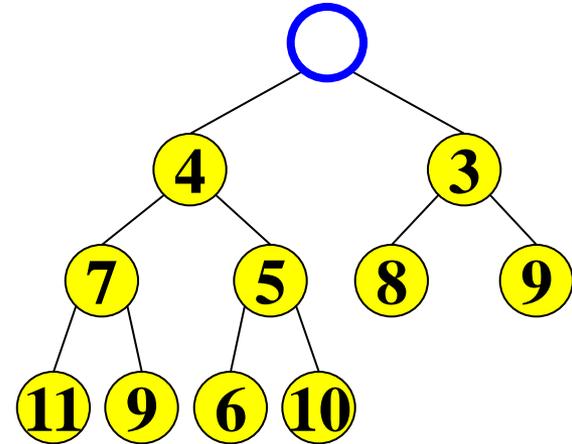

DeleteMin

1. Delete (and later return) value at root node

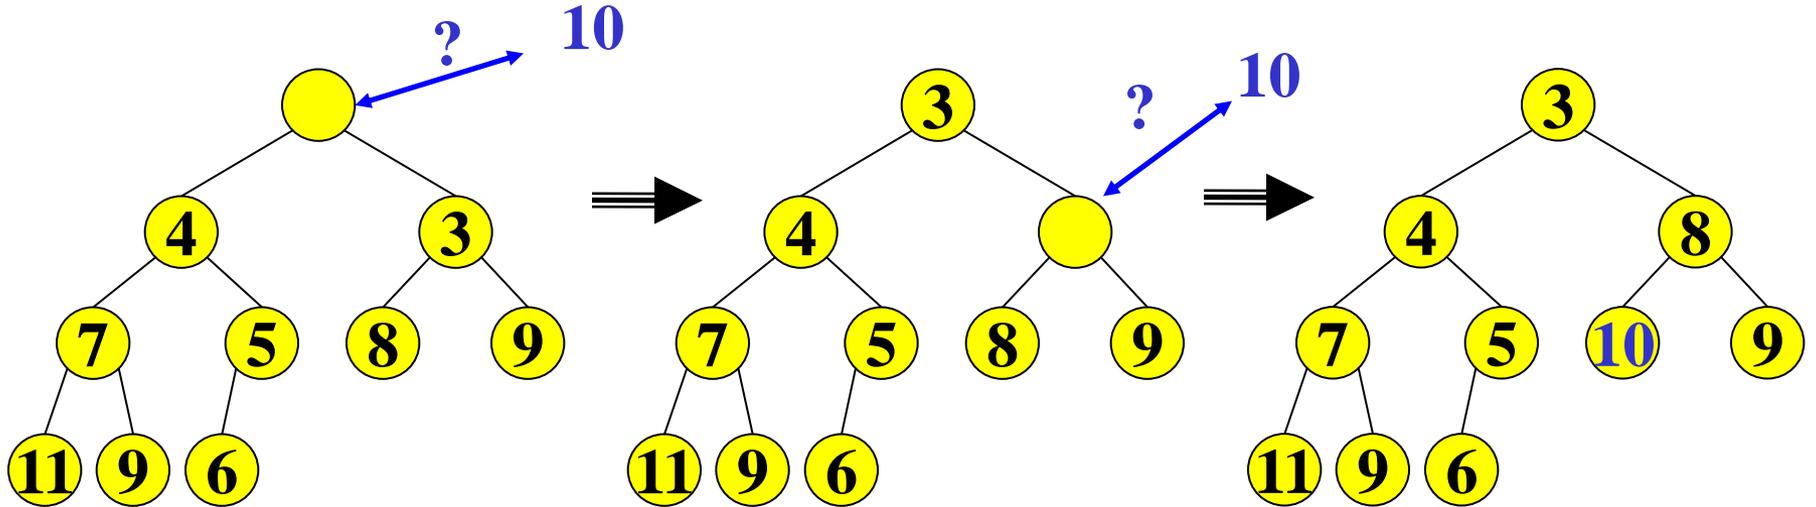

2. Restore the Structure Property

- We now have a “hole” at the root
 - Need to fill the hole with another value
- When we are done, the tree will have one less node and must still be complete

3. Restore the Heap Property

Percolate down:

- Keep comparing with both children
- Swap with lesser child and go down one level
- Done if both children are \geq item or reached a leaf node

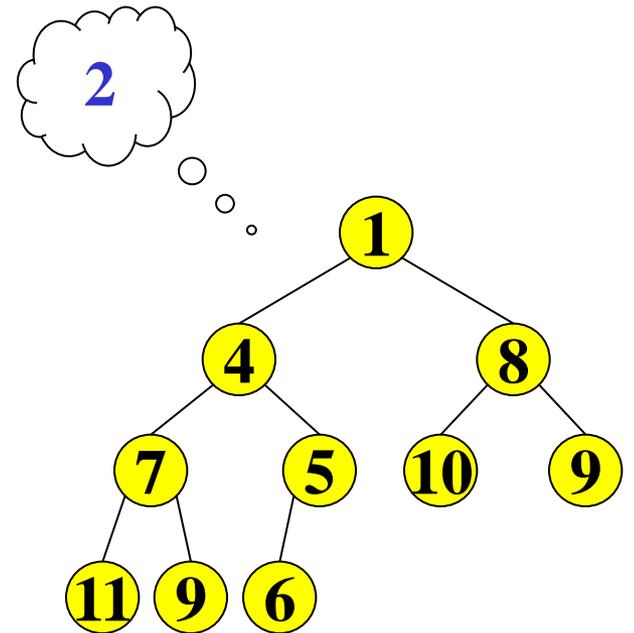

Why is this correct? What is the run time?

DeleteMin: Run Time Analysis

- Run time is $O(\text{height of heap})$
- A heap is a complete binary tree
- Height of a complete binary tree of n nodes?
 - height = $\lfloor \log_2(n) \rfloor$
- Run time of `deleteMin` is $O(\log n)$

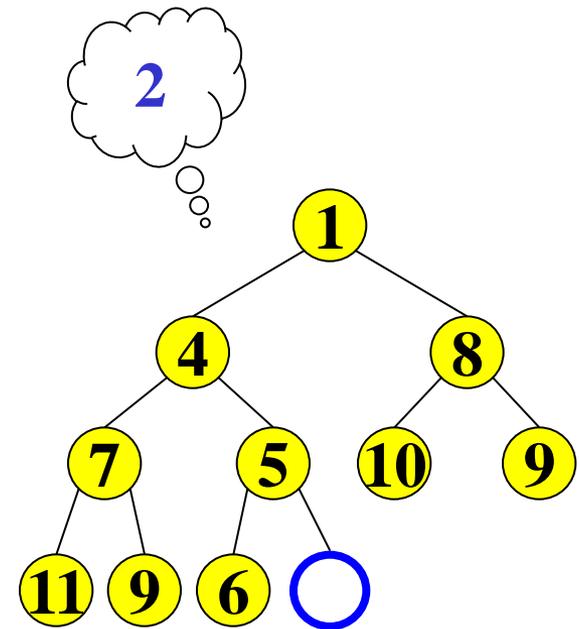

Insert

- Add a value to the tree
- Afterwards, structure and heap properties must still be correct

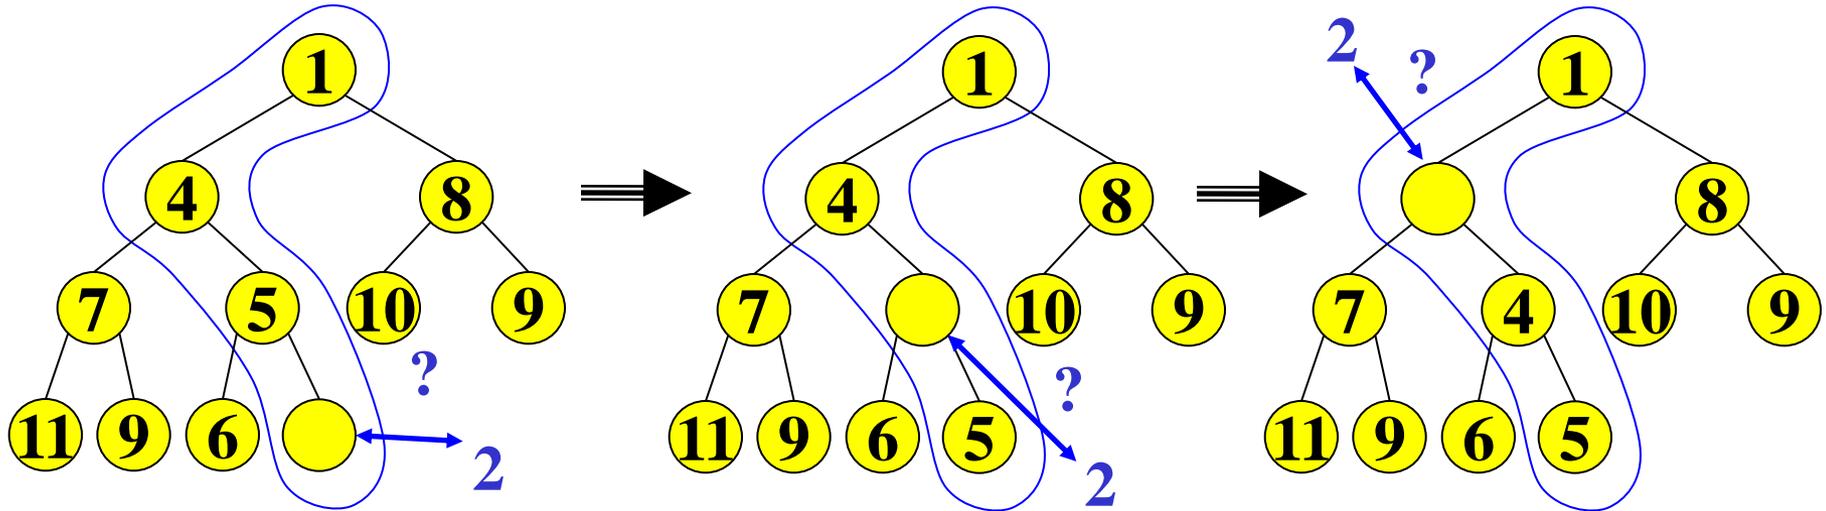

Insert: Maintain the Structure Property

- There is only one valid tree shape after we add one more node
- So put our new data there and then focus on restoring the heap property

Maintain the heap property

Percolate up:

- Put new data in new location
- If parent larger, swap with parent, and continue
- Done if parent \leq item or reached root

Why is this correct? What is the run time?

Insert: Run Time Analysis

- Like `deleteMin`, worst-case time proportional to tree height
 - $O(\log n)$
- But... `deleteMin` needs the “last used” complete-tree position and `insert` needs the “next to use” complete-tree position
 - If “keep a reference to there” then `insert` and `deleteMin` have to adjust that reference: $O(\log n)$ in worst case
 - Could calculate how to find it in $O(\log n)$ from the root given the size of the heap
 - But it’s not easy
 - And then `insert` is always $O(\log n)$, promised $O(1)$ on average (assuming random arrival of items)
- There’s a “trick”: don’t represent complete trees with explicit edges!
