More Parallel Primes-ish

Largest Factors

Last time, we found the number of primes in a range. This time, let’s find the largest factors for each number in an input array.

```
protected void compute() {
    if (hi - lo <= CUTOFF) {
        seqReplaceWithLargestFactor(arr, lo, hi);
        return;
    }
    int mid = lo + (hi - lo) / 2;
    LargestFactorTask left = new LargestFactorTask(arr, lo, mid);
    LargestFactorTask right = new LargestFactorTask(arr, mid, hi);
    left.fork();
    right.compute();
    left.join();
}
```

This problem was different than the previous ones. The goal was to apply a function to every element of an array rather than to return a result.

Maps and Reductions

Reductions

Last time, we saw several problems of the form:

INPUT: An array

OUTPUT: A combination of the array by an associative operation

The general name for this type of problem is a reduction. Examples include: max, min, has-a, first, count, sorted

Maps

We just saw a problem of the form:

INPUT: An array

OUTPUT: Apply a function to every element of that array

The general name for this type of problem is a map. You can do this with any function, because the array elements are independent.

These two types of problems are “parallel primitives” in the same way loops and if statements are “programming primitives”. Next lecture, we’ll add two more primitives.
Parallelism on Other Data Structures

So far, we’ve only tried to apply parallelism to an Array (or, equivalently, an ArrayList). What about the other data structures we know? In particular, how does ForkJoin do on:

- Linked Lists?
- Binary Trees?
- (Balanced) Binary Trees?
- n-ary Trees?

Let’s think about this with our toy problem of “sum up all the elements of the input”.

Parallelism on Balanced Trees

The idea here is to divide-and-conquer each child instead of array sub-ranges:

```java
1 compute() {
2   if (not the end of the list) {
3     fork a thread to do the rest of the elements;
4   }
5   
6   do my work
7   
8   join with the thread after me
9 }
```

But what about the sequential cut-off?

Either store the number of nodes in each subtree or approximate it with the height.

Consider the MAXIMUM problem from a few lectures ago. The best we could do in sequential-land was $O(n)$, but with parallelism, we can find the maximum element in $\Theta(lgn)$ time (with enough processors...)

Work and Span

With sequential algorithms, we often considered $T(n)$ (the runtime of the algorithm). Now, we’ll consider a more general notion:

Let $T_P(n)$ be the runtime of an algorithm using $P$ processors.

There are two important runtime quantities for a parallel algorithm:

- How long it would take if it were fully sequential (work)
- How long it would take if it were as parallel as possible (span)

**Definition (Work)**

We say work $n = T(n) - T(n)$ is the culmulative work that all processors must complete.

**Definition (Span)**

We say span $n = T(n)$ is the largest amount of work some processor must complete.

Google MapReduce and Hadoop

You may have heard of Googles MapReduce (or the open-source version Hadoop).

- Idea: Perform maps/reduces on data using many machines
- The system takes care of distributing the data and managing fault tolerance
- You just write code to map one element and reduce elements to a combined result

- Separates how to do recursive divide-and-conquer from what computation to perform
- Old idea in higher-order functional programming transferred to large-scale distributed computing
- Complementary approach to declarative queries for databases
For each "type" of tree, figure out work(−) and span(−) of findMin in terms of the number of nodes, n.

A (Parallel) Algorithm
1 int findMin(Node current) {
2 if (current is a leaf) {
3 return current.data;
4 } else {
5 if(n=1) return current.data;
6 return min(findMin(left), findMin(right));
7 }

To calculate span, we assume all calls are in parallel. We look for the longest dependence chain. We make a recurrence:

\[ \text{span}(n) = \begin{cases} 
O(1) & \text{if } n = 0 \\
\max(\text{span}(n), \text{span}(n-1)) + O(1) & \text{otherwise} 
\end{cases} \]

This ends up being the same recurrence as for work(−). Notice for the degenerate tree work(n) = span(n). This proves our intuition that we don’t get much of a (any!) speed-up with parallelism for linked lists!

A (Parallel) Algorithm
1 int findMin(Node current) {
2 if (current is a leaf) {
3 return current.data;
4 } else {
5 return min(findMin(left), findMin(right));
6 }

To calculate span, we just do our standard analysis. First, we make a recurrence:

\[ \text{span}(n) = \begin{cases} 
O(1) & \text{if } n = 0 \\
2 \times \text{work}(n/2) + O(1) & \text{otherwise} 
\end{cases} \]

Solving this recurrence gives us:

\[ \text{work}(n) = \sum_{i=0}^{\log_2(n)} 1 = \Theta(n) \]

A (Parallel) Algorithm
1 int findMin(Node current) {
2 if (current is a leaf) {
3 return current.data;
4 } else {
5 return min(findMin(left), findMin(right));
6 }

To calculate span, we take the max of the recursive calls. First, we make a recurrence:

\[ \text{span}(n) = \begin{cases} 
O(1) & \text{if } n = 1 \\
\max(\text{span}(n/2), \text{span}(n/2)) + O(1) & \text{otherwise} 
\end{cases} \]

Master Theorem says this recurrence is \( \Theta(\log n) \).

Again, this proves our intuition that parallelizing tree algorithms helps.

But what does it mean for work to be \( \Theta(n) \) and span to be \( \Theta(\log n) \)?

A (Parallel) Algorithm
1 int findMin(Node current) {
2 if (current is a leaf) {
3 return current.data;
4 } else {
5 return min(findMin(left), findMin(right));
6 }

To calculate work, we just do our standard analysis. First, we make a recurrence:

\[ \text{work}(n) = \begin{cases} 
O(1) & \text{if } n = 0 \\
\text{work}(n) + \text{work}(n-1) + O(1) & \text{otherwise} 
\end{cases} \]

Solving this recurrence gives us:

\[ \text{work}(n) = \sum_{i=0}^{n-1} 1 = \Theta(n) \]

A (Parallel) Algorithm
1 int findMin(Node current) {
2 if (current is a leaf) {
3 return current.data;
4 } else {
5 return min(findMin(left), findMin(right));
6 }

To calculate work, we just do our standard analysis. First, we make a recurrence:

\[ \text{work}(n) = \begin{cases} 
O(1) & \text{if } n = 0 \\
2 \times \text{work}(n/2) + O(1) & \text{otherwise} 
\end{cases} \]

This proves our intuition that parallelizing tree algorithms helps.

But what does it mean for work to be \( \Theta(n) \) and span to be \( \Theta(\log n) \)?

Definition (Speed-Up)
The speed-up given \( P \) processors is \( \frac{T_1}{T_P} \).

If the speed-up is \( P \) as we vary \( P \), it’s called a perfect linear speed-up.

Definition (Parallelism)
Parallelism is the maximum possible speed-up. In other words, parallelism is the speed-up when we take \( P = \infty \).

We want to decrease span without increasing work!
Okay, but we don’t have ∞ processors. . .

Consider $T_P$. We know the following:
- $T_P \geq T_1/P$, the case where all the processors are always busy.
- $T_P \geq T_\infty$, $T_\infty$ is the length of the critical path which the algorithm must go through.

So, in an optimal execution, asymptotically, we know:

$$T_P \in \Theta \left(\frac{T_1}{P} + T_\infty\right)$$

The Good News!
The ForkJoin Framework gives an expected-time guarantee of asymptotically optimal! (Want to know how? Take an advanced course!) But this is only true given some assumptions about your code:
- The program splits up the work into small and approximately equal pieces
- The program combines the pieces efficiently

Applying Our Asymptotic Bound

Minimum in a Perfect Tree
When calculating the minimum element in a tree, we had:
- $\text{work}(n) \in \Theta(n)$
- $\text{span}(n) \in \Theta(\log n)$

So, we expect the algorithm to take $O\left(\frac{n}{P} + \log n\right)$

Another Example
Suppose we have the following work and span:
- $\text{work}(n) \in \Theta(n^2)$
- $\text{span}(n) \in \Theta(n)$

So, we expect the algorithm to take $O\left(\frac{n^2}{P} + n\right)$

Amdahl’s Law

Every program has:
- parts that parallelize easily/well
- parts that don’t parallelize at all

For example, we can’t parallelize reading a linked list.

The non-parallelizable parts of a program are a huge bottleneck

So, Let’s Give Up?

Amdahl tells us that if a particular algorithm has too many sequential computations, it’s better to find a more parallelizable algorithm than to just add more processors.

We’ll see next time that unexpected problems can be solved in parallel!

Moore and Amdahl

Moore’s “Law” is an observation about the progress of the semiconductor industry:

Transistor density doubles roughly every 18 months

Amdahl’s Law is a mathematical theorem:

Diminishing returns of adding more processors

Both are incredibly important in designing computer systems
