CSE 332
Data Structures and Parallelism
Analysis of Parallel Programs
Outline

1. Parallel Primitives
2. Parallelism with Other Data Structures
3. Analyzing Parallel Algorithms
More Parallel Primes-ish

Largest Factors

Last time, we found the number of primes in a range. This time, let's find the largest factors for each number in an input array.

```java
protected void compute() {
    if (hi - lo <= CUTOFF) {
        seqReplaceWithLargestFactor(arr, lo, hi);
        return;
    }

    int mid = lo + (hi - lo) / 2;
    LargestFactorTask left = new LargestFactorTask(arr, lo, mid);
    LargestFactorTask right = new LargestFactorTask(arr, mid, hi);

    left.fork();
    right.compute();
    left.join();
}
```

This problem was different than the previous ones. The goal was to apply a function to every element of an array rather than to return a result.
Last time, we saw several problems of the form:

**INPUT:** An array  
**OUTPUT:** A combination of the array by an associative operation  
The general name for this type of problem is a **reduction**. Examples include: max, min, has-a, first, count, sorted

We just saw a problem of the form:

**INPUT:** An array  
**OUTPUT:** Apply a function to every element of that array  
The general name for this type of problem is a **map**. You can do this with any function, because the array elements are independent.

These two types of problems are “**parallel primitives**” in the same way loops and if statements are “programming primitives”. Next lecture, we’ll add two more primitives.
A Reduction

\[ A_0 \quad A_1 \quad A_2 \quad A_3 \quad A_4 \quad A_5 \quad A_6 \quad A_7 \]

A Map

\[
\begin{array}{cccccccc}
    a_0 & a_1 & a_2 & a_3 & a_4 & a_5 & a_6 & a_7 \\
\end{array}
\]

\[
\begin{array}{cccc}
    a_0 & a_1 & a_2 & a_3 \\
\end{array}
\]

\[
\begin{array}{cccc}
    a_4 & a_5 & a_6 & a_7 \\
\end{array}
\]

\[
\begin{array}{cccc}
    f(a_0) & f(a_1) & f(a_2) & f(a_3) \\
\end{array}
\]

\[
\begin{array}{cccc}
    f(a_4) & f(a_5) & f(a_6) & f(a_7) \\
\end{array}
\]
You may have heard of Google's MapReduce (or the open-source version Hadoop).

- **Idea:** Perform maps/reduces on data using many machines
  - The system takes care of distributing the data and managing fault tolerance
  - You just write code to map one element and reduce elements to a combined result

- Separates how to do recursive divide-and-conquer from what computation to perform
  - Old idea in higher-order functional programming transferred to large-scale distributed computing
  - Complementary approach to declarative queries for databases
So far, we’ve only tried to apply parallelism to an Array (or, equivalently, an ArrayList). What about the other data structures we know? In particular, how does ForkJoin do on:

- LinkedLists?
- BinaryTrees?
- (Balanced) BinaryTrees?
- $n$-ary Trees?

Let’s think about this with our toy problem of “sum up all the elements of the input”.
We wrote code that treated the array like a LinkedList last lecture.

```java
compute() {
    if (not the end of the list) {
        fork a thread to do the rest of the elements;
    }
    do my work
    join with the thread after me
}
```

The only gain we're going to get with LinkedLists is if the map function is very expensive. Then we'll at least get most of those going at once.

Naturally, as with standard algorithms on unbalanced trees, since they degenerate to linked lists, we have the same problem.
The idea here is to divide-and-conquer each child instead of array sub-ranges:

```java
1  compute() {
2      left.fork();  // Handles the entire left subtree
3      right.compute();  // Handles the entire right subtree
4
5      return left.join() + rightResult;
6  }
```

But what about the sequential cut-off?

Either store the **number of nodes** in each subtree or approximate it with the **height**

Consider the **MAXIMUM** problem from a few lectures ago. The best we could do in sequential-land was $\Omega(n)$, but with parallelism, we can find the maximum element in $\Theta(\lg n)$ time (with enough processors...)!
With sequential algorithms, we often considered $T(n)$ (the runtime of the algorithm). Now, we’ll consider a more general notion:

Let $T_P(n)$ be the runtime of an algorithm using $P$ processors.

There are two important runtime quantities for a parallel algorithm:

- How long it would take if it were fully sequential (work)
- How long it would take if it were as parallel as possible (span)

**Definition (Work)**

We say work $(n) = T_1(n) = T(n)$ is the cumulative work that all processors must complete.

**Definition (Span)**

We say span $(n) = T_\infty(n)$ is the largest amount of work some processor must complete.
Analyzing a Parallel Algorithm

For each “type” of tree, figure out work(−) and span(−) of findMin in terms of the number of nodes, \( n \).

A (Parallel) Algorithm

```java
int findMin(Node current) {
    if (current is a leaf) {
        return current.data;
    }
    return min(current.data, findMin(left), findMin(right));
}
```

Degenerate Tree

```
1
  2
   3
    4
```

Perfect Tree

```
     20
   /   \
  30   60
 /     /   \   \
40  50  70  80
```
A (Parallel) Algorithm

```
int findMin(Node current) {
    if (current is a leaf) {
        return current.data;
    }

    return min(current.data, findMin(left),
                findMin(right));
}
```

To calculate work, we just do our standard analysis. First, we make a recurrence:

\[
\text{work}(n) = \begin{cases} 
0 & \text{if } n = 0 \\
O(1) & \text{if } n = 1 \\
\text{work}(0) + \text{work}(n - 1) + O(1) & \text{otherwise}
\end{cases}
\]

Solving this recurrence gives us:

\[
\text{work}(n) = \sum_{i=0}^{n} 1 = \Theta(n)
\]
A (Parallel) Algorithm

int findMin(Node current) {
    if (current is a leaf) {
        return current.data;
    }

    return min(current.data, findMin(left), findMin(right));
}

To calculate span, we assume all calls are in parallel. We look for the longest dependence chain. We make a recurrence:

\[
\text{span}(n) = \begin{cases} 
0 & \text{if } n = 0 \\
O(1) & \text{if } n = 1 \\
\max(\text{span}(0), \text{span}(n-1)) + O(1) & \text{otherwise}
\end{cases}
\]

This ends up being the same recurrence as for work(−). Notice for the degenerate tree work(n) = span(n). This proves our intuition that we don’t get much of a (any!) speed-up with parallelism for linked lists!
A (Parallel) Algorithm

```c
int findMin(Node current) {
    if (current is a leaf) {
        return current.data;
    }

    return min(current.data, findMin(left), findMin(right));
}
```

To calculate work, we just do our standard analysis. First, we make a recurrence:

\[
work(n) = \begin{cases} 
\mathcal{O}(1) & \text{if } n = 1 \\
2 \times work(n/2) + \mathcal{O}(1) & \text{otherwise}
\end{cases}
\]

Master Theorem says this recurrence is \(\Theta(n)\).
A (Parallel) Algorithm

```c
int findMin(Node current) {
    if (current is a leaf) {
        return current.data;
    }
    return min(current.data, findMin(left), findMin(right));
}
```

To calculate span, we take the max of the recursive calls. First, we make a recurrence:

$$\text{span}(n) = \begin{cases} 
\Theta(1) & \text{if } n = 1 \\
\max(\text{span}(n/2), \text{span}(n/2)) + \Theta(1) & \text{otherwise}
\end{cases}$$

Master Theorem says this recurrence is $\Theta(\lg n)$.

Again, this proves our intuition that parallelizing tree algorithms helps.

But what does it mean for work to be $\Theta(n)$ and span to be $\Theta(\lg n)$?
Definition (Speed-Up)

The **speed-up** given $P$ processors is $\frac{T_1}{T_P}$.

If the speed-up is $P$ as we vary $P$, it’s called a **perfect linear speed-up**.

Definition (Parallelism)

**Parallelism** is the **maximum possible speed-up**. In other words, parallelism is the speed-up when we take $P = \infty$.

We want to decrease span without increasing work!
Consider \( T_P \). We know the following:

- \( T_P \geq \frac{T_1}{P} \), the case where all the processors are always busy.
- \( T_P \geq T_\infty \), \( T_\infty \) is the length of the critical path which the algorithm must go through.

So, in an optimal execution, **asymptotically**, we know:

\[
T_P \in \Theta\left(\frac{T_1}{P} + T_\infty\right)
\]

The Good News!

The ForkJoin Framework gives an expected-time guarantee of asymptotically optimal! (Want to know how? Take an advanced course!) But this is only true given some assumptions about your code:

- The program splits up the work into small and approximately equal pieces
- The program combines the pieces efficiently
Applying Our Asymptotic Bound

Minimum in a Perfect Tree

When calculating the minimum element in a tree, we had:

- \( \text{work}(n) \in \Theta(n) \)
- \( \text{span}(n) \in \Theta(\lg n) \)

So, we expect the algorithm to take \( O\left(\frac{n}{P} + \lg n\right) \)

Another Example

Suppose we have the following work and span:

- \( \text{work}(n) \in \Theta(n^2) \)
- \( \text{span}(n) \in \Theta(n) \)

So, we expect the algorithm to take \( O\left(\frac{n^2}{P} + n\right) \)
Every program has:
- parts that parallelize easily/well
- parts that don’t parallelize at all

For example, we can’t parallelize reading a linked list.

The non-parallelizable parts of a program are a huge bottleneck
Split the work up into two pieces: the “parallelizable” piece and the “non-parallelizable” piece. Let $S$ be the inherently sequential work.

$$T_1 = S \times \text{work}(n) + (1 - S) \times \text{work}(n)$$

Suppose we get a perfect linear speed-up on the parallelizable work:

$$T_P = S \times \text{work}(n) + \frac{(1 - S) \times \text{work}(n)}{P}$$

So, the speed-up is:

$$\frac{T_1}{T_P} = \frac{1}{S + \frac{1-S}{P}}$$

The Bad News
Suppose 33% of a program is sequential. Then, the absolute best speed-up we can get is:

$$\frac{T_1}{T_{\infty}} = \frac{1}{0.33} = 3$$

That means infinitely many processors won’t help us get more than a 3 times speed-up!
Amdahl tells us that if a **particular algorithm** has too many sequential computations, it's better to find a **more parallelizable** algorithm than to just add more processors.

We’ll see next time that unexpected problems can be solved in parallel!

---

**Moore and Amdahl**

Moore’s “Law” is an observation about the progress of the semiconductor industry:

Transistor density doubles roughly every 18 months

Amdahl’s Law is a mathematical theorem:

Diminishing returns of adding more processors

Both are incredibly important in designing computer systems
