CSE 373: Data Structures and Algorithms

Lecture 22: Introduction to Multithreading and Parallelism

Instructor: Lilian de Greef
Quarter: Summer 2017
Today:

Introduction to multithreading and parallelism
  • Parallelism vs Concurrency
  • Shared memory
  • Threads in Java
So far most or all of your study of computer science has assumed

*One thing happened at a time*

Called *sequential programming* – everything part of one sequence
It’s all been lies!
Well, not all lies...

But most computers these days have multiple cores, and most languages support using them.

These additional cores create major opportunities (and challenges!)

• Divide work among **threads of execution** and **synchronize** (coordinate) them

• Parallel activity can provide speed-up i.e. more **throughput**: work done per unit time

• May need to support **concurrent access** to data (multiple threads operating on data **at the same time**
What to do with multiple processors?

• Run multiple totally different programs at the same time (Though could already do that with time-slicing)

• Do multiple things at once in one program
  • Requires rethinking everything from asymptotic complexity to how to implement data-structure operations
Parallelism vs. Concurrency

**Parallelism:**
Use extra resources to solve a problem faster

**Concurrency:**
Correctly and efficiently manage access to shared resources

There is some connection:
- Common to use *threads* for both
- If parallel computations need access to shared resources, then the concurrency needs to be managed

We will focus on parallelism, avoiding concurrency issues
An analogy

CS1 idea: A program is like a recipe for a cook
  • One cook who does one thing at a time! (*Sequential*)

Parallelism:
  • Have lots of potatoes to slice?
  • Hire helpers, hand out potatoes and knives
  • But too many chefs and you spend all your time coordinating

Concurrency:
  • Lots of cooks making different things, but only 4 stove burners
  • Want to allow access to all 4 burners, but not cause spills or incorrect burner settings
Our model for (unshared) memory

- Stack
- Heap < (not data structures)

Local variables live here

Objects live here!
Shared memory

The model we will assume is shared memory with explicit threads.

Old story: A running program has

- One **program counter** (tracks which current statement is executing)
- One **call stack** (made of stack frames that hold local variables)
- Objects in the heap created by memory allocation (i.e., `new`)
  - (nothing to do with data structure called a heap)
- **Static fields** belong to the class and not an instance (or object) of the class. Only one for all instances of a class.

```java
int x = 2
```
Shared memory

The model we will assume is shared memory with explicit threads

New story:
- A set of threads, each with its own program counter & call stack
  - No access to another thread’s local variables
- Threads can (implicitly) share static fields / objects
  - To communicate, write somewhere

Unshared: locals and control

Shared: objects and static fields
Our Needs

To write a shared-memory parallel program, need new primitives from a programming language or library

• Ways to create and *run multiple things at once*
  • Let’s call these things *threads*

• Ways for threads to *share memory*
  • Often just have threads with references to the same objects

• Ways for threads to *coordinate (a.k.a. synchronize)*
  • A way for one thread to *wait* for another to finish
  • [Other features needed in practice for concurrency]

*avoid a race condition!*
Race Condition Example

- You have $500 in bank account
- Someone transfers $200 to you. Thread A updates your balance.
- At the same time, you spend $50. Thread B updates your balance.

Thread A
- See $500
- $500 + $200 = 700
- Update to 700

Thread B
- See $500
- $500 - $50 = 450
- Update 450

Done in wrong order → end up with $450
Java basics

Learn `java.lang.Thread`
- In real life, use Java’s ForkJoin Framework instead!

To get a new thread running:
1. Define a subclass `t` of `java.lang.Thread`, **overriding** `run`
2. Create an object of class `t`
3. Call that object’s `start` method
   - `start` sets off a new thread, using `run` as its “main”

What if we instead called the `run` method of `t`?
- This would just be a normal method call, in the current thread

Let’s see how to share memory and coordinate via an example...
Parallelism idea: Example

Example: Sum elements of a large array
Idea: Have 4 threads simultaneously sum 1/4 of the array
• Warning: This is an inferior first approach, but it’s usually good to start with something naïve
  works

• Create 4 thread objects, each given a portion of the work
• Call start() on each thread object to actually run it in parallel
• Wait for threads to finish using join()
• Add together their 4 answers for the final result
First attempt: create Thread subclass

class SumThread extends java.lang.Thread {

    int lo; // arguments
    int hi;
    int[] arr;

    int ans = 0; // result

    SumThread(int[] a, int l, int h) {
        lo=l; hi=h; arr=a;
    }

    public void run() { //override must have this type
        for(int i=lo; i < hi; i++)
            ans += arr[i];
    }
}

Because we must override a no-arguments/no-result run, we use fields to communicate across threads
First attempt, continued (wrong)

class SumThread extends java.lang.Thread {
    int lo, int hi, int[] arr; // arguments
    int ans = 0; // result
    SumThread(int[] a, int l, int h) { ... }
    public void run(){ ... } // override
}

int sum(int[] arr){ // can be a static method
    int len = arr.length;
    int ans = 0;
    SumThread[] ts = new SumThread[4];
    for(int i=0; i < 4; i++) // do parallel computations
        ts[i] = new SumThread(arr,i*len/4,(i+1)*len/4);
    for(int i=0; i < 4; i++) // combine results
        ans += ts[i].ans;
    return ans;
}

// Need to call start()!

array
new thread objects
Second attempt (still wrong)

class SumThread extends java.lang.Thread {
    int lo, int hi, int[] arr; // arguments
    int ans = 0; // result
    SumThread(int[] a, int l, int h) { ... }
    public void run(){ ... } // override
}

int sum(int[] arr){ // can be a static method
    int len = arr.length;
    int ans = 0;
    SumThread[] ts = new SumThread[4];
    for(int i=0; i < 4; i++){ // do parallel computations
        ts[i] = new SumThread(arr,i*len/4,(i+1)*len/4);
        ts[i].start(); // start not run
    }
    for(int i=0; i < 4; i++) // combine results
        ans += ts[i].ans;
    return ans;
}
Third attempt (correct in spirit)

```java
class SumThread extends java.lang.Thread {
    int lo, int hi, int[] arr; // arguments
    int ans = 0; // result
    SumThread(int[] a, int l, int h) { ... }
    public void run() { ... } // override
}

int sum(int[] arr){ // can be a static method
    int len = arr.length;
    int ans = 0;
    SumThread[] ts = new SumThread[4];
    for(int i=0; i < 4; i++) { // do parallel computations
        ts[i] = new SumThread(arr, i*len/4, (i+1)*len/4);
        ts[i].start();
    }
    for(int i=0; i < 4; i++) {
        ts[i].join(); // wait for helper to finish!
        ans += ts[i].ans;
    }
    return ans;
}
```

Java detail: code has 1 compile error because `join` may throw `java.lang.InterruptedException`

In basic parallel code, should be fine to catch-and-exit.
What’s Happening?

1. Start with one thread
What’s Happening?

2. Main thread reaches `sum()` method, creates 4 new threads
What’s Happening?

3. Each new thread begins its `start()` method, and iterates over its section of the array.
What’s Happening?

4. Each new thread may end at different times, so the main thread must wait until they are all done (calls `join()`) before summing them up
What’s Happening?

1. Start with one thread
2. Main thread reaches sum() method, creates 4 new threads
3. Each new thread begins its `start()` method, and iterates over its section of the array
4. Each new thread may end at different times, so the main thread must wait until they are all done (calls `join()`) before summing them up
What’s Happening?
Join (not the most descriptive word)

• The **join** method is valuable for coordinating this kind of computation
  • Caller blocks until/unless the receiver is done executing (meaning the call to **run** returns)
  • Else we would have a **race condition** on **ts[i].ans** (answer would depend on what finishes first)

• This style of parallel programming is called “fork/join”
Shared memory?

• Fork-join programs (thankfully) do not require much focus on sharing memory among threads

• But in languages like Java, there is memory being shared. In our example:
  • lo, hi, arr fields written by “main” thread, read by helper thread
  • ans field written by helper thread, read by “main” thread

• When using shared memory, you must avoid race conditions
  • We will stick with join to do so
How many threads to use?

Several reasons why this is a poor parallel algorithm

1. Want code to be reusable and efficient across platforms
   • “Forward-portable” as core count grows
   • So at the very least, parameterize by the # of threads

```java
int sum(int[] arr, int numTs)
{
    int ans = 0;
    SumThread[] ts = new SumThread[numTs];
    for(int i=0; i < numTs; i++){
        ts[i] = new SumThread(arr,(i*arr.length)/numTs,
                               ((i+1)*arr.length)/numTs);
        ts[i].start();
    }
    for(int i=0; i < numTs; i++) {
        ts[i].join();
        ans += ts[i].ans;
    }
    return ans;
}
```
How many threads to use?

2. Want to use (only) processors “available to you now”
   
   - Not used by other programs or threads in your program
     
     - Maybe caller is also using parallelism
     
     - Available cores can change even while your threads run

```cpp
// numThreads == numProcessors??
int sum(int[] arr, int numTs){
    ...
}
```

Bad idea if need some processors for other things
How many threads to use?

3. Though unlikely for \textit{sum}, in general subproblems may take significantly different amounts of time

\begin{itemize}
  \item Example: Apply method $f$ to every array element, but maybe $f$ is much slower for some data items
    \begin{itemize}
      \item Example: Is a large integer prime?
    \end{itemize}
  \item If we create 4 threads and all the slow data is processed by 1 of them, we won’t get nearly a 4x speedup
    \begin{itemize}
      \item Example of a \textit{load imbalance}
    \end{itemize}
\end{itemize}
How many threads to use?

A solution to all these problems is to use lots of threads, far more than the number of processors

- But this will require changing our algorithm
- [And using a different Java library]

1. Forward-portable: Lots of helpers each doing a small piece
2. Processors available: Hand out “work chunks” as you go
3. Load imbalance: No problem if slow thread scheduled early enough
   - Variation probably small anyway if pieces of work are small
Naïve algorithm

Suppose we create 1 thread to process every 1000 elements

```java
int sum(int[] arr){
    ... int numThreads = arr.length / 1000;
    SumThread[] ts = new SumThread[numThreads];
    ...}
```

Then combining results will have `arr.length / 1000` additions
- Linear in size of array (with constant factor 1/1000)
- Previously we had only 4 pieces (constant in size of array)

In the extreme, if we create 1 thread for every 1 element, the loop to combine results has length-of-array iterations

*good/bad?* just like original sequential algorithm
A better idea

This is straight-forward to implement using divide-and-conquer

• Parallelism for the recursive calls
• Each thread creates two new threads, lets them run and then sums up their answer
• Below some threshold (when the array gets small enough) thread just runs
  
  +/- +/- +/- 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 
  + + + + + + 

Similar to MergeSort or Quicksort

cutoff to switch alg.
Divide-and-conquer to the rescue!

class SumThread extends java.lang.Thread {
    int lo; int hi; int[] arr; // arguments
    int ans = 0; // result
    SumThread(int[] a, int l, int h) { ... }
    public void run(){ // override
        if(hi - lo < SEQUENTIAL_CUTOFF)
            for(int i=lo; i < hi; i++)
                ans += arr[i];
        else {
            SumThread left = new SumThread(arr,lo,(hi+lo)/2);
            SumThread right = new SumThread(arr,(hi+lo)/2,hi);
            left.start();
            right.start();
            left.join(); // don’t move this up a line - why?
            right.join();
            ans = left.ans + right.ans;
        }
    }
}

int sum(int[] arr){
    SumThread t = new SumThread(arr,0,arr.length);
    t.run();
    return t.ans;
}
Divide-and-conquer really works

• Divide-and-conquer parallelizes the result-combining
  • If you have enough processors, total time is height of the tree: $O(\log n)$
    (optimal, exponentially faster than sequential $O(n)$)
Being realistic

• In theory, you can divide down to single elements, do all your result-combining in parallel and get optimal speedup (P is number of processors)
  • Total time $O(n/P + \log n)$

• In practice, creating all those threads and communicating swamps the savings, so:
  • Use a sequential cutoff, e.g. around 500-1000 threads
    • Eliminates almost all the recursive thread creation (bottom levels of tree)
  • Instead of creating two recursive threads; create one and do the other “yourself”
    • Cuts the number of threads created by another 2x
Being realistic, part 2

• Even with all this care, Java’s threads are too “heavyweight”
  • Constant factors that affect performance, especially space overhead
  • Creating 20,000 Java threads is just a bad idea 😊

• The ForkJoin Framework is designed to meet the needs of divide-and-conquer fork-join parallelism
  • In the Java standard libraries
  • Library’s implementation is a fascinating but advanced topic
  • Names of methods and how to use them slightly different
