

CSE 401 – Compilers

ASTs, Modularity, and the Visitor Pattern

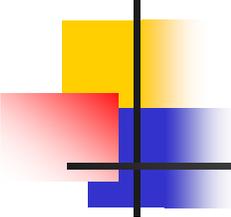

Hal Perkins

Winter 2010

Modularity

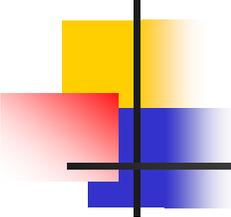

- Classic slogans:
 - Do one thing well
 - Minimize coupling, maximize cohesion
 - Isolate operations/abstractions in modules
 - Hide implementation details
- OK, so where's the typechecker module in MiniJava?

Operations on ASTs

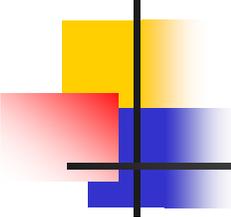

- In a typical compiler, we may want to do these things with the AST:
 - Print a readable dump of the tree
 - Do static semantic analysis
 - Type checking
 - Verify that things are declared and initialized properly
 - Etc. etc. etc. etc.
 - Perform optimizing transformations on the tree
 - Generate code from the tree, or
 - Generate another IR from the tree for further processing (often flatten to a linear IR)

Where do the Operations Go?

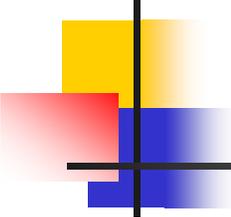

- Pure “object-oriented” style
 - Smart AST nodes
 - Each node knows how to perform every operation on itself

```
public class WhileNode extends StmtNode {  
    public typeCheck(...);  
    public generateCode(...);  
    public prettyPrint(...);  
    ...  
}
```

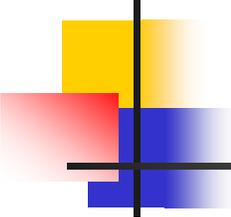

Critique

- This is nicely encapsulated – all details about a `WhileNode` are hidden in that class
- But there are issues with modularity
 - What if we want to add a new operation?
 - Have to open up every node class
 - Details of each individual operation (printing, type checking) are scattered
 - Poor locality; hard to share information needed by related operations

Modularity Issues

- Smart nodes make sense if the set of operations is relatively fixed, particularly if we expect to need flexibility to add new kinds of nodes
- Example: graphics system
 - Operations: draw, move, iconify, highlight
 - Objects: textbox, scrollbar, canvas, menu, dialog box, plus new objects defined as the system evolves

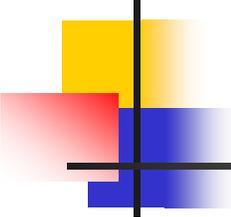

Modularity in a Compiler

- Abstract syntax does not change frequently over time
 - \therefore Kinds of nodes are relatively stable
- As a compiler evolves, it is more common to modify or add operations
 - Can we modularize each operation (type checker, code generation) so its components are together?
 - Can we avoid having to change node classes when we modify or add an operation?

Two Views of Modularity

	Type check	Optimize	Generate x86	Flatten	Print
IDENT	X	X	X	X	X
exp	X	X	X	X	X
while	X	X	X	X	X
if	X	X	X	X	X
Binop	X	X	X	X	X
...					

	draw	move	iconify	highlight	transmogrify
circle	X	X	X	X	X
text	X	X	X	X	X
canvas	X	X	X	X	X
scroll	X	X	X	X	X
dialog	X	X	X	X	X
...					

Visitor Pattern

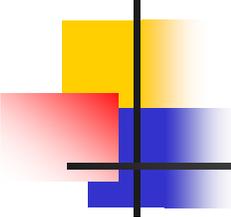

- Idea: Package each operation in a separate class
 - Contains separate methods for each AST node kind
 - Examples: print class, type check class, codegen class
- Create one instance of this **visitor** class
 - Sometimes called a “function object”
- Include a generic “accept visitor” method in every node class
- To perform the operation, pass a “visitor object” around the AST during a traversal
 - This object contains separate methods to process each AST node type

Avoiding instanceof

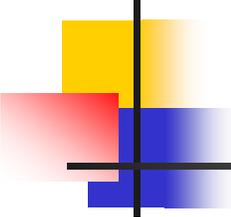

- Next issue: we'd like to avoid huge if-elseif nests to check the node type in the visitor

```
void checkTypes(ASTNode p) {  
    if (p instanceof WhileNode) { ... }  
    else if (p instanceof IfNode) { ... }  
    else if (p instanceof BinExp) { ... } ...
```
- Solution: Include an overloaded "visit" method for each node type and get the node to call back to the correct visitor operation for that kind of node(!)
 - "Double dispatch"

One More Issue

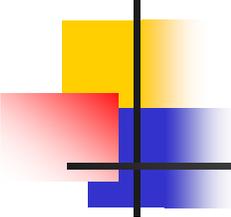

- We want to be able to add new operations easily, so the nodes shouldn't know anything specific about the actual visitor class(es)
- Solution: an abstract Visitor interface
 - AST nodes include "accept visitor" method for the interface
 - Specific operations (type check, code gen) are implementations of this interface

Visitor Interface

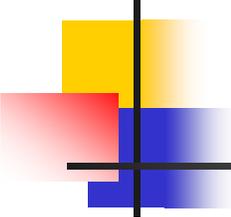

```
interface Visitor {  
    // overload visit for each AST node type  
    public void visit(WhileNode s);  
    public void visit(IfNode s);  
    public void visit(BinExp e);  
    ...  
}
```

- Aside: The result type can be whatever is convenient, doesn't have to be void

Specific class TypeCheckVisitor

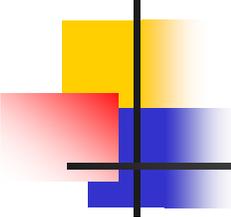

```
// Perform type checks on the AST
public class TypeCheckVisitor implements Visitor {
    // override operations for each node type
    public void visit(BinExp e) {
        e.exp1.accept(this); e.exp2.accept(this);
        // do additional processing on e before or after
    }
    public void visit(WhileNode s) { ... }
    public void visit(IfNode s) { ... }
    ...
}
```

Visitor Method in AST Nodes

- Add a new method to class ASTNode (base class or interface describing all AST nodes)

```
public abstract class ASTNode {  
    ...  
    // accept a visit from a Visitor object v  
    public abstract void accept(Visitor v);  
    ...  
}
```

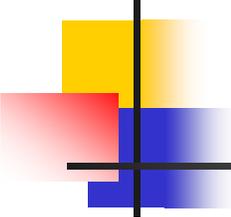

Override Accept Method in Each Specific AST Node Class

- Example

```
public class WhileNode extends StmtNode {  
    ...  
    // accept a visit from a Visitor object v  
    public void accept(Visitor v) {  
        v.visit(this); // call correct method in visitor v  
    }  
    ...  
}
```

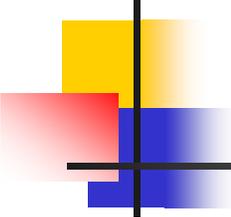

- Key points

- Visitor object passed as a parameter to WhileNode
- WhileNode calls visit(WhileNode) – i.e., the correct method for this kind of node, and executes a visit method defined in the class of visitor object v.

Encapsulation

- A visitor object often needs to be able to access state in the AST nodes
 - \therefore May need to expose more node state than we might do to otherwise
 - Overall a good tradeoff – better modularity
 - (plus, the nodes are relatively simple data objects anyway)

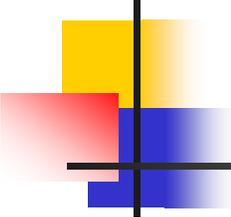

Composite Objects

- If the node contains references to subnodes, we often visit them first (i.e., pass the visitor along in a depth-first traversal of the AST)

```
public class WhileNode extends StmtNode {
    Expr exp; Stmt stmt; // children
    ...
    // accept a visit from Visitor object v
    public void accept(Visitor v) {
        this.exp.accept(v);
        this.stmt.accept(v);
        v.visit(this);
    }
    ...
}
```

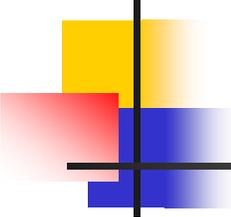

- Other traversals can be added if needed

Visitor Actions

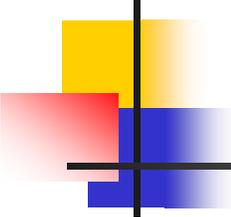

- A visitor function has a reference to the node it is visiting (the parameter)
 - `∴` can access subtrees via that node
- It's also possible for the visitor object to contain local instance data, used to accumulate information during the traversal
 - Effectively “global data” shared by visit methods

```
public class TypeCheckVisitor extends NodeVisitor {
    public void visit(WhileNode s) { ... }
    public void visit(IfNode s) { ... }
    ...
    private <visitor local state shared by methods>;
}
```

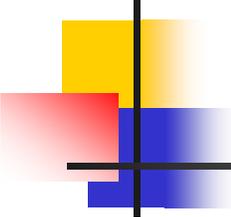

Responsibility for the Traversal

- Possible choices
 - The node objects drive the traversal (as done above)
 - The visitor object (the visitor has access to the node, so it can traverse any substructure it wishes)
 - Some sort of iterator object
- In a compiler, the first choice can handle many common cases
 - But if you need to do something different, do it!

Ouch!

- Does it have to be this complicated?
- What we're trying to do: 2-level overloading + dispatch during generic traversal
 - First, need to get correct method for kind of node
 - Then need to get method belonging to correct visitor (print, type check, generate code)
- If our language supports double-dispatch we could express this directly
 - But in Java and conventional O-O languages, only the first parameter (receiver) controls dispatch
- Another solution: multimethods. Research at UW, see papers by Chambers and colleagues
 - But, alas, not part of Java, C#, etc.
