What’s in a process?

• A process consists of (at least):
  – an address space
  – the code for the running program
  – the data for the running program
  – an execution stack and stack pointer (SP)
    • traces state of procedure calls made
  – the program counter (PC), indicating the next instruction
  – a set of general-purpose processor registers and their values
  – a set of OS resources
    • open files, network connections, sound channels, …

• That’s a lot of concepts bundled together!

Concurrency

• Imagine a web server, which might like to handle multiple requests concurrently
  – While waiting for the credit card server to approve a purchase for one client, it could be retrieving the data requested by another client from disk, and assembling the response for a third client from cached information

• Imagine a web client (browser), which might like to initiate multiple requests concurrently
  – The CSE home page has 46 "src=..." html commands, each of which is going to involve a lot of sitting around! Wouldn’t it be nice to be able to launch these requests concurrently?

• Imagine a parallel program running on a multiprocessor, which might like to concurrently employ multiple processors
  – For example, multiplying a large matrix – split the output matrix into k regions and compute the entries in each region concurrently using k processors

What’s needed?

• In each of these examples of concurrency (web server, web client, parallel program):
  – Everybody wants to run the same code
  – Everybody wants to access the same data
  – Everybody has the same privileges
  – Everybody uses the same resources (open files, network connections, etc.)

• But you’d like to have multiple hardware execution states:
  – an execution stack and stack pointer (SP)
  – traces state of procedure calls made
  – the program counter (PC), indicating the next instruction
  – a set of general-purpose processor registers and their values

How could we achieve this?

• Given the process abstraction as we know it:
  – fork several processes
  – cause each to map to the same address space to share data
  • see the shmget() system call for one way to do this (kind of)

• This is like making a pig fly – it’s really inefficient
  – space: PCB, page tables, etc.
  – time: creating OS structures, fork and copy addr space, etc.

• Some equally bad alternatives for some of the cases:
  – Entirely separate web servers
  – Asynchronous programming (non-blocking I/O) in the web client (browser)

Can we do better?

• Key idea:
  – separate the concept of a process (address space, etc.)
  – from that of a minimal "thread of control" (execution state: PC, etc.)

• This execution state is usually called a thread, or sometimes, a lightweight process
Threads and processes

- Most modern OS's (Mach, Chorus, NT, modern UNIX) therefore support two entities:
  - the process, which defines the address space and general process attributes (such as open files, etc.)
  - the thread, which defines a sequential execution stream within a process
- A thread is bound to a single process
  - processes, however, can have multiple threads executing within them
  - sharing data between threads is cheap: all see the same address space
  - creating threads is cheap too!
- Threads become the unit of scheduling
  - processes are just containers in which threads execute

The design space

- MS/DOS: one thread/process, many processes
- Java: one thread/process, many processes
- Older UNIXes: one thread/process, many processes
- Mach, NT, Chorus, Linux, …: many threads/process, many processes

(old) Process address space

- process address space
- stack (dynamic allocated mem)
- heap (dynamic allocated mem)
- static data (data segment)
- code (text segment)
- SP
- PC

(new) Process address space with threads

- process address space
- thread 1 stack
- thread 2 stack
- thread 3 stack
- heap (dynamic allocated mem)
- static data (data segment)
- code (text segment)
- SP (T1)
- SP (T2)
- SP (T3)
- PC (T2)
- PC (T1)
- PC (T3)

Process/thread separation

- Concurrency (multithreading) is useful for:
  - handling concurrent events (e.g., web servers and clients)
  - building parallel programs (e.g., matrix multiply, ray tracing)
  - improving program structure (the Java argument)
- Multithreading is useful even on a uniprocessor
  - even though only one thread can run at a time
- Supporting multithreading – that is, separating the concept of a process (address space, files, etc.) from that of a minimal thread of control (execution state), is a big win
  - creating concurrency does not require creating new processes
  - “faster / better / cheaper”

"Where do threads come from, Mommy?"

- Natural answer: the kernel is responsible for creating/managing threads
  - for example, the kernel call to create a new thread would
  - allocate an execution stack within the process address space
  - create and initialize a Thread Control Block
  - stick it on the ready queue
  - we call these kernel threads
Threads can also be managed at the user level (that is, entirely from within the process)
- a library linked into the program manages the threads
- because threads share the same address space, the thread manager doesn’t need to manipulate address spaces (which only the kernel can do)
- threads differ (roughly) only in hardware contexts (PC, SP, registers), which can be manipulated by user-level code
- the thread package multiplexes user-level threads on top of kernel thread(s), which it treats as “virtual processors”
- we call these user-level threads

Kernel threads
- OS now manages threads and processes
  - all thread operations are implemented in the kernel
  - OS schedules all of the threads in a system
  - if one thread in a process blocks (e.g., on I/O), the OS knows about it, and can run other threads from that process
  - possible to overlap I/O and computation inside a process
- Kernel threads are cheaper than processes
  - less state to allocate and initialize
  - But, they’re still pretty expensive for fine-grained use (e.g., orders of magnitude more expensive than a procedure call)
  - thread operations are all system calls
    - context switch
    - argument checks
  - must maintain kernel state for each thread

User-level threads
- To make threads cheap and fast, they need to be implemented at the user level
  - managed entirely by user-level library, e.g., libpthreads.a
- User-level threads are small and fast
  - each thread is represented simply by a PC, registers, a stack, and a small thread control block (TCB)
  - creating a thread, switching between threads, and synchronizing threads are done via procedure calls
    - no kernel involvement is necessary!
  - user-level thread operations can be 10-100x faster than kernel threads as a result

Performance example
- On a 700MHz Pentium running Linux 2.2.16:
  - Processes
    - fork/exit: 251 µs
  - Kernel threads
    - pthread_create()/pthread_join(): 94 µs (2.5x faster)
  - User-level threads
    - pthread_create()/pthread_join: 4.5 µs (another 20x faster)

- On a DEC SRC Firefly running Ultrix, 1989
  - Processes
    - fork/exit: 251 µs / 11,300 µs
  - Kernel threads
    - pthread_create()/pthread_join(): 94 µs / 948 µs (12x faster)
  - User-level threads
    - pthread_create()/pthread_join: 4.5 µs / 34 µs (another 28x faster)

User-level thread implementation
- The kernel believes the user-level process is just a normal process running code
  - But, this code includes the thread support library and its associated thread scheduler
- The thread scheduler determines when a thread runs
  - it uses queues to keep track of what threads are doing: run, ready, wait
    - just like the OS and processes
    - but, implemented at user-level as a library
Thread interface

- This is taken from the POSIX pthreads API:
  - `t = pthread_create(attributes, start_procedure)`
  - creates a new thread of control
  - new thread begins executing at start_procedure
  - `pthread_cond_wait(condition_variable)`
    - the calling thread blocks, sometimes called thread_block()
  - `pthread_signa(condition_variable)`
    - starts the thread waiting on the condition variable
  - `pthread_exit()`
    - terminates the calling thread
  - `pthread_wait(t)`
    - waits for the named thread to terminate

How to keep a user-level thread from hogging the CPU?

- Strategy 1: force everyone to cooperate
  - a thread willingly gives up the CPU by calling `yield()`
  - `yield()` calls into the scheduler, which context switches to another ready thread
  - what happens if a thread never calls `yield()`?

- Strategy 2: use preemption
  - scheduler requests that a timer interrupt be delivered by the OS periodically
    - usually delivered as a UNIX signal (man signal)
    - signals are just like software interrupts, but delivered to user-level by the OS instead of delivered to OS by hardware
  - at each timer interrupt, scheduler gains control and context switches as appropriate

Thread context switch

- Very simple for user-level threads:
  - save context of currently running thread
    - push machine state onto thread stack
  - restore context of the next thread
    - pop machine state from next thread’s stack
  - return as the new thread
    - execution resumes at PC of next thread

This is all done by assembly language

- it works at the level of the procedure calling convention
  - thus, it cannot be implemented using procedure calls
  - e.g., a thread might be preempted (and then resumed) in the middle of a procedure call

What if a thread tries to do I/O?

- The kernel thread “powering” it is lost for the duration of the (synchronous) I/O operation!
- Could have one kernel thread “powering” each user-level thread
  - no real difference from kernel threads – “common case” operations (e.g., synchronization) would be quick
- Could have a limited-size “pool” of kernel threads “powering” all the user-level threads in the address space
  - the kernel will be scheduling its threads oblivious to what’s going on at user-level

What if the kernel preempts a thread holding a lock?

- Other threads will be unable to enter the critical section and will block (stall)
  - tradeoff, as with everything else
- Solving this requires coordination between the kernel and the user-level thread manager
  - “scheduler activations”
    - a research paper from UW with huge effect on industry
    - each process can request one or more kernel threads
      - process is given responsibility for mapping user-level threads onto kernel threads
      - kernel promises to notify user-level before it suspends or destroys a kernel thread
    - ACM TOCS 10,1

Summary

- You really want multiple threads per address space
- Kernel threads are much more efficient than processes, but they’re still not cheap
  - all operations require a kernel call and parameter verification
- User-level threads are:
  - fast as blazes
  - great for common-case operations
    - creation, synchronization, destruction
  - can suffer in uncommon cases due to kernel obliviousness
    - I/O
    - preemption of a lock-holder
- Scheduler activations are the answer
  - pretty subtle though
