Goals of memory management

- Allocate memory resources among competing processes, maximizing memory utilization and system throughput
- Provide isolation between processes
  - We have come to view "addressability" and "protection" as inextricably linked, even though they're really orthogonal
- Provide a convenient abstraction for programming (and for compilers, etc.)

Tools of memory management

- Base and limit registers
- Swapping
- Paging (and page tables and TLB's)
- Segmentation (and segment tables)
- Page faults => page fault handling => virtual memory
- The policies that govern the use of these mechanisms

Today's desktop and server systems

- The basic abstraction that the OS provides for memory management is virtual memory (VM)
  - Efficient use of hardware (real memory)
  - VM enables programs to execute without requiring their entire address space to be resident in physical memory
  - Many programs don't need all of their code or data at once (or ever -- branches they never take, or data they never read/write)
  - No need to allocate memory for it, OS should adjust amount allocated based on run-time behavior
  - Program flexibility
    - Programs can execute on machines with less RAM than they "need"
    - On the other hand, paging is really slow, so must be minimized!
  - Protection
    - Virtual memory isolates address spaces from each other
    - One process cannot name addresses visible to others; each process has its own isolated address space

VM requires hardware and OS support

- MMU's, TLB's, page tables, page fault handling, ...
- Typically accompanied by swapping, and at least limited segmentation

A trip down Memory Lane …

- Why?
  - Because it's instructive
  - Because embedded processors (98% or more of all processors) typically don't have virtual memory
  - Because some aspects are pertinent to allocating portions of a virtual address space -- e.g., malloc()
- First, there was job-at-a-time batch programming
  - programs used physical addresses directly
  - OS loads job (perhaps using a relocating loader to "offset" branch addresses), runs it, unloads it
  - what if the program wouldn't fit into memory?
    - manual overlays!
- An embedded system may have only one program!
• **Swapping**
  - save a program’s entire state (including its memory image) to disk
  - allows another program to be run
  - first program can be swapped back in and re-started right where it was

• The first timesharing system, MIT’s “Compatible Time Sharing System” (CTSS), was a uni-programmed swapping system
  - only one memory-resident user
  - upon request completion or quantum expiration, a swap took place
  - bow wow wow … but it worked!

• **Then came multiprogramming**
  - multiple processes/jobs in memory at once
  - to overlap I/O and computation between processes/jobs, easing the task of the application programmer
  - memory management requirements:
    - protection: restrict which addresses processes can use, so they can’t stomp on each other
    - fast translation: memory lookups must be fast, in spite of the protection scheme
    - fast context switching: when switching between jobs, updating memory hardware (protection and translation) must be quick

Virtual addresses for multiprogramming

• To make it easier to manage memory of multiple processes, make processes use virtual addresses (which is not what we mean by "virtual memory" today!)""
  - virtual addresses are independent of location in physical memory (RAM) where referenced data lives
    - OS determines location in physical memory
    - instructions issued by CPU reference virtual addresses
      - e.g., pointers, arguments to load/store instructions, PC …
    - virtual addresses are translated by hardware into physical addresses (with some setup from OS)

• The set of virtual addresses a process can reference is its address space
  - many different possible mechanisms for translating virtual addresses to physical addresses
    - we’ll take a historical walk through them, ending up with our current techniques
  - Note: We are not yet talking about paging, or virtual memory
    - Only that the program issues addresses in a virtual address space, and these must be translated to reference memory (the physical address space)
    - For now, think of the program as having a contiguous virtual address space that starts at 0, and a contiguous physical address space that starts somewhere else

Old technique #1: Fixed partitions

• Physical memory is broken up into fixed partitions
  - partitions may have different sizes, but partitioning never changes
  - hardware requirement: base register, limit register
    - physical address = virtual address + base register
    - base register loaded by OS when it switches to a process
  - how do we provide protection?
    - if (physical address > base + limit) then…?
• Advantages
  - Simple
• Problems
  - internal fragmentation: the available partition is larger than what was requested
  - external fragmentation: two small partitions left, but one big job — what sizes should the partitions be??

Mechanics of fixed partitions
Old technique #2: Variable partitions

- Obvious next step: physical memory is broken up into partitions dynamically – partitions are tailored to programs
  - hardware requirements: base register, limit register
  - physical address = virtual address + base register
  - how do we provide protection?
    - if (physical address > base + limit) then…?
- Advantages
  - no internal fragmentation
    - simply allocate partition size to be just big enough for process (assuming we know what that is!)
- Problems
  - external fragmentation
    - as we load and unload jobs, holes are left scattered throughout physical memory
    - slightly different than the external fragmentation for fixed partition systems

Dealing with fragmentation

- Compact memory by copying
  - Swap a program out
  - Re-load it, adjacent to another
  - Adjust its base register
  - “Lather, rinse, repeat”
  - Ugh

Modern technique: Paging

- Solve the external fragmentation problem by using fixed sized units in both physical and virtual memory
- Solve the internal fragmentation problem by making the units small

Life is easy …

- For the programmer …
  - Processes view memory as a contiguous address space from bytes 0 through N – a virtual address space
  - N is independent of the actual hardware
  - In reality, virtual pages are scattered across physical memory frames – not contiguous as earlier
    - Virtual-to-physical mapping
    - This mapping is invisible to the program
- For the memory manager …
  - Efficient use of memory, because very little internal fragmentation
  - No external fragmentation at all
    - No need to copy big chunks of memory around to coalesce free space

For the protection system

- One process cannot “name” another process’s memory – there is complete isolation
  - The virtual address 0xDEADBEEF maps to different physical addresses for different processes

Note: Assume for now that all pages of the address space are resident in memory – no “page faults”
Address translation

- Translating virtual addresses
  - A virtual address has two parts: virtual page number & offset
  - Virtual page number (VPN) is an index into a page table
  - Page table entry contains page frame number (PFN)
  - Physical address isPFN::offset

- Page tables
  - Managed by the OS
  - One page table entry (PTE) per page in virtual address space
    - I.e., one PTE per VPN
  - Map virtual page number (VPN) to page frame number (PFN)
    - VPN is simply an index into the page table

Paging (K-byte pages)

Example of address translation

- Assume 32 bit addresses
  - Assume page size is 4KB (4096 bytes, or 2^12 bytes)
  - VPN is 20 bits long (2^20 VPNs), offset is 12 bits long

- Let’s translate virtual address 0x13325328
  - VPN is 0x13325, and offset is 0x328
  - Assume page table entry 0x13325 contains value 0x03004
  - Page frame number is 0x03004
  - Physical address = PFN::offset = 0x03004328

Page Table Entries – an opportunity!

- As long as there’s a PTE lookup per memory reference, we might as well add some functionality
  - We can add protection
    - A virtual page can be read-only, and result in a fault if a store to it is attempted
    - Some pages may not map to anything — a fault will occur if a reference is attempted
  - We can add some “accounting information”
    - Can’t do anything fancy, since address translation must be fast
    - Can keep track of whether or not a virtual page is being used, though
      - This will help the paging algorithm, once we get to paging

Page Table Entries (PTE’s)

- PTE’s control mapping
  - The valid bit says whether or not the PTE can be used
  - It says whether or not a virtual address is valid
    - It is checked each time a virtual address is used
  - The referenced bit says whether the page has been accessed
    - It is set when a page has been read or written to
  - The modified bit says whether or not the page is dirty
    - It is set when a write to the page has occurred
  - The protection bits control which operations are allowed
    - Read, write, execute
  - The page frame number determines the physical page
    - Physical page start address = PFN
Paging advantages

- Easy to allocate physical memory
  - Physical memory is allocated from free list of frames
- To allocate a frame, just remove it from the free list
- External fragmentation is not a problem
  - Managing variable-sized allocations is a huge pain in the neck
    - "Buddy system"
- Leads naturally to virtual memory
  - Entire program need not be memory resident
  - Take page faults using "valid" bit
  - All "chunks" are the same size (page size)
  - But paging was originally introduced to deal with external fragmentation, not to allow programs to be partially resident

Paging disadvantages

- Can still have internal fragmentation
  - Process may not use memory in exact multiples of pages
  - But minor because of small page size relative to address space size
- Memory reference overhead
  - 2 references per address lookup (page table, then memory)
  - Solution: use a hardware cache to absorb page table lookups
- Translation lookaside buffer (TLB) – next class
- Memory required to hold page tables can be large
  - Need one PTE per page in virtual address space
  - 32 bit AS with 4KB pages = 2^20 PTEs = 1,048,576 PTEs
  - 4 bytes/PTE = 4MB per page table
  - OS’s have separate page tables per process
  - 25 processes = 100MB of page tables
  - Solution: page the page tables (!!!)
    - (oh, my brain hurts…more later)

Segmentation
(We will be back to paging soon!)

- Paging
  - Mitigates various memory allocation complexities (e.g., fragmentation)
  - View an address space as a linear array of bytes
  - Divide it into pages of equal size (e.g., 4KB)
  - Use a page table to map virtual pages to physical page frames
    - Page (logical) => page frame (physical)
- Segmentation
  - Partition an address space into logical units
  - Stack, code, heap, subroutines, …
  - A virtual address is <segment #, offset>

What’s the point?

- More "logical"
  - Absent segmentation, a linker takes a bunch of independent modules that call each other and linearizes them
  - They are really independent; segmentation treats them as such
- Facilitates sharing and reuse
  - A segment is a natural unit of sharing – a subroutine or function
- A natural extension of variable-sized partitions
  - Variable-sized partition = 1 segment/process
  - Segmentation = many segments/process

Hardware support

- Segment table
  - Multiple base/limit pairs, one per segment
  - Segments named by segment #, used as index into table
    - A virtual address is <segment #, offset>
  - Offset of virtual address added to base address of segment to yield physical address

Segment lookups
Pros and cons

• Yes, it’s “logical” and it facilitates sharing and reuse
• But it has all the horror of a variable partition system
  – except that linking is simpler, and the “chunks” that must be
    allocated are smaller than a “typical” linear address space
• What to do?

Combining segmentation and paging

• Can combine these techniques
  – x86 architecture supports both segments and paging
• Use segments to manage logical units
  – segments vary in size, but are typically large (multiple pages)
• Use pages to partition segments into fixed-size chunks
  – each segment has its own page table
    • there is a page table per segment, rather than per user address
      space
  – memory allocation becomes easy once again
    • no contiguous allocation, no external fragmentation

<table>
<thead>
<tr>
<th>Segment #</th>
<th>Page #</th>
<th>Offset within page</th>
</tr>
</thead>
<tbody>
<tr>
<td>Offset within segment</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

• Linux:
  – 1 kernel code segment, 1 kernel data segment
  – 1 user code segment, 1 user data segment
  – all of these segments are paged

• Note: this is a very limited/boring use of segments!
