## What's "in" a process?

- A process consists of (at least):
  - An **address space**, containing
    - the code (instructions) for the running program
    - the data for the running program (static data, heap data, stack)
  - **CPU state**, consisting of
    - The program counter (PC), indicating the next instruction
    - The stack pointer
    - Other general purpose register values
  - A set of **OS resources**
    - open files, network connections, sound channels, ...
- In other words, it's all the stuff you need to run the program
  - or to re-start it, if it's interrupted at some point

## The OS gets control because of ...

- **Trap**: Program executes a syscall
- **Exception**: Program does something unexpected (e.g., page fault)
- **Interrupt**: A hardware device requests service

3

## PCBs and CPU state

- When a process is running, its CPU state is inside the CPU
  - PC, SP, registers
  - CPU contains current values
- When the OS gets control (trap, exception, interrupt), the OS saves the CPU state of the running process in that process's PCB
  - when the OS returns the process to the running state, it loads the hardware registers with values from that process's PCB – general purpose registers, stack pointer, instruction pointer
- This is called a **context switch**

4

## The syscall

- How do user programs do something privileged?
  - e.g., how can you write to a disk if you can't execute an I/O instructions?
- User programs must call an OS procedure – that is, get the OS to do it for them
  - OS defines a set of system calls
  - User-mode program executes system call instruction with a parameter indicating the specific function desired
- Syscall instruction
  - Like a protected procedure call

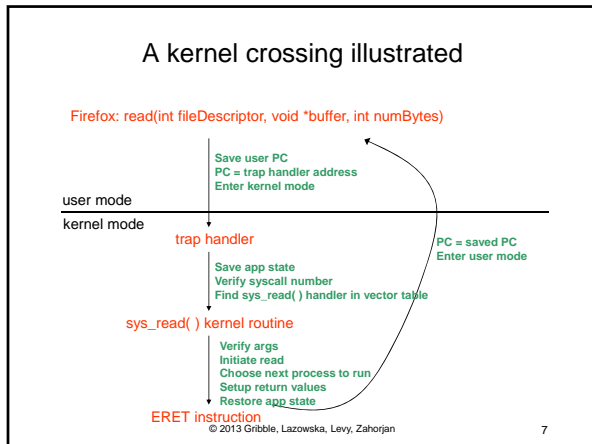

© 2013 Gribble, Lazowska, Levy, Zahorjan

5

- The syscall instruction atomically:
  - Saves the current PC
  - Sets the execution mode to privileged
  - Sets the PC to a handler address
- With that, it's a lot like a local procedure call
  - Caller puts arguments in a place callee expects (registers or stack)
    - One of the args is a syscall number, indicating which OS function to invoke
  - Callee (OS) saves caller's state (registers, other control state) so it can use the CPU
  - OS function code runs
    - OS must verify caller's arguments (e.g., pointers)
  - OS returns using a special instruction
    - Automatically sets PC to return address and sets execution mode to user

6

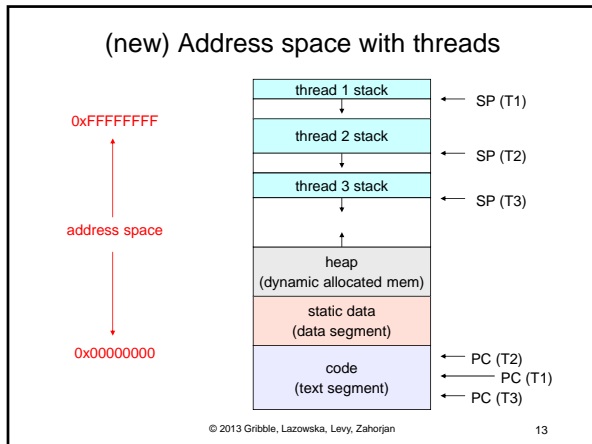

- ### Interrupts and exceptions work the same way as traps
- Transition to kernel mode
  - Save state of running process in PCB
  - Handler routine deals with whatever occurred
  - Choose a next process to run
  - Restore that process's CPU state from its PCB
  - Execute an instruction that returns you to user mode at the appropriate instruction

- ### The OS kernel is not a process
- It's just a block of code!
  - (In a microkernel OS, many things that you normally think of as the operating system execute as user-mode processes. But the OS kernel is just a block of code.)

- ### Threads
- Key idea:
    - separate the concept of a **process** (address space, OS resources)
    - ... from that of a minimal **"thread of control"** (execution state: stack, stack pointer, program counter, registers)
  - This execution state is usually called a **thread**, or sometimes, a **lightweight process**
-

- ### Kernel threads
- OS now manages threads *and* processes / address spaces
    - all thread operations are implemented in the kernel
    - OS schedules all of the threads in a system
      - if one thread in a process blocks (e.g., on I/O), the OS knows about it, and can run other threads from that process
      - possible to overlap I/O and computation *inside* a process
  - Kernel threads are cheaper than processes
    - less state to allocate and initialize
  - But, they're still pretty expensive for fine-grained use
    - orders of magnitude more expensive than a procedure call
    - thread operations are all system calls
      - context switch
      - argument checks
    - must maintain kernel state for each thread
- © 2013 Gribble, Lazowska, Levy, Zahorjan 14

- ### In the beginning ...
- Fork a process
    - Creates an address space that's a clone of the parent, with one thread
    - There's a PCB that describes the address space and the OS resources
    - There's a TCB that holds the CPU state and is the unit of scheduling
    - The TCB and the PCB are linked – e.g., so the OS knows which set of page tables to use when scheduling a particular thread
  - First thread can create additional threads
    - OS creates a new TCB, initializes CPU state (an entry point must be provided in the "create" syscall)
- © 2013 Gribble, Lazowska, Levy, Zahorjan 15

- You really want multiple threads per address space
  - Kernel threads are much more efficient than processes, but they're still not cheap
    - all operations require a kernel call and parameter validation
  - User-level threads are:
    - really fast/cheap
    - great for common-case operations
      - creation, synchronization, destruction
    - can suffer in uncommon cases due to kernel obliviousness
      - I/O
      - preemption of a lock-holder
  - Scheduler activations are an answer
    - pretty subtle though
