Interrupts

* **Interrupt**
  * Hardware or software
  * Hardware interrupts caused by devices signaling CPU
  * Software interrupts caused by code

* **Exception**
  * Unintentional software interrupt
  * E.g. errors, divide-by-zero, general protection fault

* **Trap**
  * Intentional software interrupt
  * Controlled method of entering kernel mode
  * System calls
Interrupt handling

※ Execution of current process halts

※ CPU switches from user mode to kernel mode, saving process state (registers, stack pointer, program counter)

※ CPU looks up interrupt handler in table and executes it

※ When the interrupt handler finishes, the CPU restores the process state, switches back to user mode, and resumes execution
Interrupt handling

What happens if there is another interrupt during the handler?
- The kernel disables interrupts before entering a handler routine?
- Preemption

What happens if an interrupt fires while they are disabled?
- The kernel queues interrupts for later processing
System calls

* Provide userspace applications with controlled access to OS services
* Requires special hardware support on the CPU to detect a certain system call instruction and trap to the kernel
* x86 uses the INT X instruction, X in [0,255]
System call control flow

* User application calls a user-level library routine (gettimeofday(), read(), exec(), etc.)
* Invokes system call through stub, which specifies the system call number. From unistd.h:
  
  ```
  #define __NR_getpid 172
  __SYSCALL(__NR_getpid, sys_getpid)
  ```
* This generally causes an interrupt, trapping to kernel
* Kernel looks up system call number in syscall table, calls appropriate function
* Function executes and returns to interrupt handler, which returns the result to the userspace process
System call control flow

Specifics have changed since this diagram was created, but the idea is still the same
Linux Syscall Specifics

- The syscall handler is generally defined in `arch/x86/kernel/entry_[32|64].S`
- In the Ubuntu kernel I am running, `entry_64.S` contains `ENTRY(system_call)`, which is where the syscall logic starts
- There used to be "int" and "iret" instructions, but those have been replaced by "sysenter" and "sysexit", which provide similar functionality.
Project 1

✿ Due: April 24 at 11:59 PM.

✿ Three parts of varying difficulty:
  ✿ Write a simple shell in C
  ✿ Add a new system call and track state in kernel structures to make it work
  ✿ Write a library through which the system call can be invoked

✿ Turn in code plus a write-up related to what you learned/should have learned
The CSE451 shell

- Print out prompt
- Accept input
- Parse input
- If built-in command
  - Do it directly
- Else spawn new process
  - Launch specified program
  - Wait for it to finish
- Repeat

```
CSE451Shell% /bin/date
Wed Apr 31 21:58:55 PDT 2013
CSE451Shell% pwd
/root
CSE451Shell% cd /
CSE451Shell% pwd
/
CSE451Shell% exit
```
CSE451 shell hints

In your shell:

* Use `fork` to create a child process
* Use `execvp` to execute a specified program
* Use `wait` to wait until child process terminates

Useful library functions (see man pages):

* Strings: `strcmp`, `strncpy`, `strtok`, `atoi`
* I/O: `fgets` or (preferrably) `readline`
* Error reporting: `perror`
* Environment variables: `getenv`
Advice from a previous TA:

- Try running a few commands in your completed shell and then type exit. If it doesn’t exit the first time, you’re doing something wrong
- `echo $?` prints the last exit code, so you can check your exit code against what is expected.
- Check the return values of all library/system calls. They might not be working as you expect.
- Each partner in your group should contribute some work to each piece or you won’t end up understanding the big picture
Adding a system call

Add `execcounts` system call to Linux:

- Purpose: collect statistics
- Count number of times a process and all of its descendents call the `fork`, `vfork`, `clone`, and `exec` system calls

Steps:

- Modify kernel to keep track of this information
- Add `execcounts` to return the counts to the user
- Use `execcounts` in your shell to get this data from kernel and print it out
Programming in kernel mode

- Your shell will operate in user mode
- Your system call code will be in the Linux kernel, which operates in kernel mode
- Be careful - different programming rules, conventions, etc.
Kernel programming

- Can’t use application libraries (e.g. libc)
  - No printf—use prink instead
- Use only headers/functions exposed by the kernel
- Don’t forget you’re in kernel space
- You cannot trust user space
- For example, you should validate user buffers (look in kernel source for what other syscalls, e.g., `gettimeofday` do)
Kernel development hints

* Use find + grep as a starting point to find interesting code

```sh
find . -type f -name "*.h" -exec grep -n \ 
gettimeofday {} +
```

* Pete Hornyack (a previous TA) put together a tutorial on using ctags and cscope to cross-reference type definitions:

Kernel development hints

* Use Git to collaborate with your project partners
  * There is a guide to getting Git set up for use with project 1 on the website:
  * Overview of use:
    * Create a shared repository in `/projects/instr/13sp/cse451/X`, where X is your group’s letter
    * Check the project’s kernel source into the repository
    * Have each group member check out the kernel source, make modifications to it as necessary, and check in their changes
    * See the web page for more information

* Git makes it easy to find any files you’ve changed.
Project 1 development

Option 1: Use VMWare on a Windows lab machine
- Can use forkbomb for kernel compilation (fast)
- ...or use the VM itself for kernel compilation (slow?)
- The VM files are not preserved once you log out of the Windows machine, so copy/git push your work to attu, your shared repository, or some other “safe” place

Option 2: Use your own machine
- Can use VMWare, VirtualBox, or your VMM of choice
- See the “VM information” page on the website for getting this set up:
Once you have built the kernel, copy the resulting bzImage file to your VM and overwrite /boot/vmlinuz-3.8.3-201.cse451custom

Reboot with sudo shutdown -r now

If your kernel fails to boot, pick a different kernel from the menu to get back into the VM

While inside the running VM, use the dmesg command to print out the kernel log (your printks will show up here—use grep to find the ones you care about)
Project 1 development

* Instructions will be coming out soon for using Qemu to test the kernels
  * Much more convenient than Vmware
  * It will run in a terminal window
  * You can debug the kernel from your host machine using GDB
  * It’s a bit trickier to set up ... but good stuff to know if you plan to get into backend dev
  * Forkbomb is a Qemu virtual machine!
Time Left?

We could chat about

- Linux kernel basics – modules, compiling, configuring
- Some nice features the Linux kernel provides
- The weather
- Workflow tricks (automation is your friend)
