A THEORY FOR RECORD LINKAGE*

IVAN P. FELLEGI AND ALAN B. SUNTER

Dominion Bureau of Statistics

A mathematical model is developed to provide a theoretical framework for a computer-oriented solution to the problem of recognizing those records in two files which represent identical persons, objects or events (said to be matched).

A comparison is to be made between the recorded characteristics and values in two records (one from each file) and a decision made as to whether or not the members of the comparison-pair represent the same person or event, or whether there is insufficient evidence to justify either of these decisions at stipulated levels of error. These three decisions are referred to as link (A1), a non-link (A2), and a possible link (A3). The first two decisions are called positive dispositions.

The two types of error are defined as the error of the decision A1 when the members of the comparison pair are in fact unmatched, and the error of the decision A3 when the members of the comparison pair are, in fact matched. The probabilities of these errors are defined as

\[ \mu = \sum_{\gamma \in \Gamma} u(\gamma)P(A_1 | \gamma) \]

and

\[ \lambda = \sum_{\gamma \in \Gamma} m(\gamma)P(A_3 | \gamma) \]

respectively where \( u(\gamma) \), \( m(\gamma) \) are the probabilities of realizing \( \gamma \) (a comparison vector whose components are the coded agreements and disagreements on each characteristic) for unmatched and matched record pairs respectively. The summation is over the whole comparison space \( \Gamma \) of possible realizations.

A linkage rule assigns probabilities \( P(A_1 | \gamma) \), \( P(A_3 | \gamma) \), and \( P(A_3 | \gamma) \) to each possible realization of \( \gamma \in \Gamma \). An optimal linkage rule \( L(\mu, \lambda, \Gamma) \) is defined for each value of \( (\mu, \lambda) \) as the rule that minimizes \( P(A_3) \) at those error levels. In other words, for fixed levels of error, the rule minimizes the probability of failing to make positive dispositions.

A theorem describing the construction and properties of the optimal linkage rule and two corollaries to the theorem which make it a practical working tool are given.

1. INTRODUCTION

The necessity for comparing the records contained in a file \( L_A \) with those in a file \( L_B \) in an effort to determine which pairs of records relate to the same population unit is one which arises in many contexts, most of which can be categorized as either (a) the construction or maintenance of a master file for a population, or (b) merging two files in order to extend the amount of information available for population units represented in both files.

The expansion of interest in the problem in the last few years is explained by three main factors:

1) the creation, often as a by-product of administrative programmes, of large files which require maintenance over long periods of time and which often contain important statistical information whose value could be increased by linkage of individual records in different files;

2) increased awareness in many countries of the potential of record linkage for medical and genetic research;
3) advances in electronic data processing equipment and techniques which make it appear technically and economically feasible to carry out the huge amount of operational work in comparing records between even medium-sized files.

A number of computer-oriented record linkage operations have already been reported in the literature ([4], [5], [6], [7], [8], [11], [12], [13]) as well as at least two attempts to develop a theory for record linkage ([1], [3]). The present paper is, the authors hope, an improved version of their own earlier papers on the subject ([2], [9], [10]). The theory, developed along the lines of classical hypothesis testing, leads to a linkage rule which is quite similar to the intuitively appealing approach of Newcombe ([4], [5], [6]).

The approach of the present paper is to create a mathematical model within the framework of which a theory is developed to provide guidance for the handling of the linkage problem. Some simplifying assumptions are introduced and some practical problems are examined.

2. THEORY

There are two populations A and B whose elements will be denoted by a and b respectively. We assume that some elements are common to A and B. Consequently the set of ordered pairs

\[ A \times B = \{ (a, b); a \in A, b \in B \} \]

is the union of two disjoint sets

\[ M = \{ (a, b); a = b, a \in A, b \in B \} \]

and

\[ U = \{ (a, b); a \neq b, a \in A, b \in B \} \]

which we call the matched and unmatched sets respectively.

Each unit in the population has a number of characteristics associated with it (e.g. name, age, sex, marital status, address at different points in time, place and date of birth, etc.). We assume now that there are two record generating processes, one for each of the two populations. The result of a record generating process is a record for each member of the population containing some selected characteristics (e.g. age at a certain date, address at a certain date, etc.). The record generating process also introduces some errors and some incompleteness into the resulting records (e.g. errors of reporting or failure to report, errors of coding, transcribing, keypunching, etc.). As a result two unmatched members of A and B may give rise to identical records (either due to errors or due to the fact that an insufficient number of characteristics are included in the record) and, conversely, two matched (identical) members of A and B may give rise to different records. We denote the records corresponding to members of A and B by \( a(a) \) and \( b(b) \) respectively.

We also assume that simple random samples, denoted by \( A \) and \( B \), respectively, are selected from each of A and B. We do not, however, exclude the
possibility that $A_1 = A$ and $B_1 = B$. The two given files, $L_1$ and $L_2$, are considered to be the result of the application of the record generating process to $A$ and $B$, respectively. For simplicity of notation we will drop the subscript $s$.

The first step in attempting to link the records of the two files (i.e. identifying the records which correspond to matched members of $A$ and $B$) is the comparison of records. The result of comparing two records, is a set of codes encoding such statements as "name is the same," "name is the same and it is Brown," "name disagrees," "name missing on one record," "agreement on city part of address, but not on street," etc. Formally we define the comparison vector as a vector function of the records $a(a), b(b)$:

$$
\gamma[a(a), b(b)] = \{ \gamma_1[a(a), b(b)], \ldots, \gamma_K[a(a), b(b)] \}
$$

It is seen that $\gamma$ is a function on $A \times B$. We shall write $\gamma(a, b)$ or $\gamma(a, b)$ or simply $\gamma$ as it serves our purpose. The set of all possible realizations of $\gamma$ is called the comparison space and denoted by $\Gamma$.

In the course of the linkage operation we observe $\gamma(a, b)$ and want to decide either that $(a, b)$ is a matched pair $(a, b) \in M$ (call this decision, denoted by $A_1$, a positive link) or that $(a, b)$ is an unmatched pair $(a, b) \in U$ (call this decision, denoted by $A_2$, a positive non-link). There will be however some cases in which we shall find ourselves unable to make either of these decisions at specified levels of error (as defined below) so that we allow a third decision, denoted $A_3$, a possible link.

A linkage rule $L$ can now be defined as a mapping from $\Gamma$, the comparison space, onto a set of random decision functions $D = \{ D(\gamma) \}$ where

$$
d(\gamma) = \{ P(A_1 | \gamma), P(A_2 | \gamma), P(A_3 | \gamma) \}; \gamma \in \Gamma
$$

and

$$
\sum_{i=1}^{3} P(A_i | \gamma) = 1.
$$

In other words, corresponding to each observed value of $\gamma$, the linkage rule assigns the probabilities for taking each of the three possible actions. For some or even all of the possible values of $\gamma$ the decision function may be a degenerate random variable, i.e. it may assign one of the actions with probability equal to 1.

We have to consider the levels of error associated with a linkage rule. We assume, for the time being, that a pair of records $[\alpha(a), \beta(b)]$ is selected for comparison according to some probability process from $L_1 \times L_2$ (this is equivalent to selecting a pair of elements $(a, b)$ at random from $A \times B$, due to the construction of $L_1$ and $L_2$). The resulting comparison vector $\gamma[\alpha(a), \beta(b)]$ is a random variable. We denote the conditional probability of $\gamma$, given that $(a, b) \in M$ by $m(\gamma)$. Thus

$$
m(\gamma) = P[\gamma[\alpha(a), \beta(b)] | (a, b) \in M] = \sum_{(a,b)\in M} P[\gamma[\alpha(a), \beta(b)]] \cdot P[(a, b) | M].
$$

Similarly we denote the conditional probability of $\gamma$, given that $(a, b) \in U$ by $u(\gamma)$. Thus
There are two types of error associated with a linkage rule. The first occurs when an unmatched comparison is linked and has the probability

\[ P(A_1 | U) = \sum_{\gamma \in \Gamma} u(\gamma) \cdot P(A_1 | \gamma). \]  

(8)

The second occurs when a matched comparison is non-linked and has the probability

\[ P(A_2 | M) = \sum_{\gamma \in \Gamma} m(\gamma) \cdot P(A_2 | \gamma). \]  

(9)

A linkage rule on the space \( \Gamma \) will be said to be a linkage rule at the levels \( \mu, \lambda \ (0 < \mu < 1 \) and \( 0 < \lambda < 1 \) and denoted by \( L(\mu, \lambda, \Gamma) \) if

\[ P(A_1 | U) = \mu \]  

(10)

and

\[ P(A_2 | M) = \lambda. \]  

(11)

Among the class of linkage rules on \( \Gamma \) which satisfy (10) and (11) the linkage rule \( L(\mu, \lambda, \Gamma) \) will be said to be the optimal linkage rule if the relation

\[ P(A_2 | L) \leq P(A_2 | L') \]  

(12)

holds for every \( L'(\mu, \lambda, \Gamma) \) in the class.

In explanation of our definition we note that the optimal linkage rule maximizes the probabilities of positive dispositions of comparisons (i.e. decisions \( A_1 \) and \( A_2 \)) subject to the fixed levels of error in (10) and (11) or, put differently, it minimizes the probability of failing to make a positive disposition. This seems a reasonable approach since in applications the decision \( A_2 \) will require expensive manual linkage operations; alternatively, if the probability of \( A_2 \) is not small, the linkage process is of doubtful utility.

It is not difficult to see that for certain combinations of \( \mu \) and \( \lambda \) the class of linkage rules satisfying (10) and (11) is empty. We admit only those combinations of \( \mu \) and \( \lambda \) for which it is possible to satisfy equations (10) and (11) simultaneously with some set \( D \) of decision functions as defined by (4) and (5). For a more detailed discussion of admissibility see Appendix 1. At this point it is sufficient to note that a pair of values \( (\mu, \lambda) \) will be inadmissible only if one or both of the members are too large, and that in this case we would always be happy to reduce the error levels.

2.1. A fundamental theorem

We first define a linkage rule \( L_0 \) on \( \Gamma \). We start by defining a unique ordering of the (finite) set of possible realizations of \( \gamma \).

If any value of \( \gamma \) is such that both \( m(\gamma) \) and \( u(\gamma) \) are equal to zero, then the (unconditional) probability of realizing that value of \( \gamma \) is equal to zero.
hence it need not be included in \( \Gamma \). We now assign an order arbitrarily to all \( \gamma \) for which \( m(\gamma) > 0 \) but \( u(\gamma) = 0 \).

Next we order all remaining \( \gamma \) in such a way that the corresponding sequence of

\[
m(\gamma)/u(\gamma)
\]

is monotone decreasing. When the value of \( m(\gamma)/u(\gamma) \) is the same for more than one \( \gamma \) we order these \( \gamma \) arbitrarily.

We index the ordered set \( \{ \gamma \} \) by the subscript \( i \); \( i = 1, 2, \ldots, N_\Gamma \); and write \( u_i = u(\gamma_i) \); \( m_i = m(\gamma_i) \).

Let \( (\mu, \lambda) \) be an admissible pair of error levels and choose \( n \) and \( n' \) such that

\[
\sum_{i=1}^{n-1} u_i < \mu \leq \sum_{i=1}^{n} u_i \tag{13}
\]

\[
\sum_{i=n'}^{N_\Gamma} m_i \geq \lambda > \sum_{i=n'+1}^{N_\Gamma} m_i \tag{14}
\]

where \( N_\Gamma \) is the number of points in \( \Gamma \).

We assume for the present that when (13) and (14) are satisfied we have \( 1 < n \leq n' - 1 < N_\Gamma \). This will ensure that the levels \( (\mu, \lambda) \) are admissible. Let \( L_0(\mu, \lambda, \Gamma) \) denote the linkage rule defined as follows: having observed a comparison vector, \( \gamma \), take action \( A_1 \) (positive link) if \( i \leq n - 1 \), action \( A_2 \) when \( n < i \leq n' - 1 \), and action \( A_3 \) (positive non-link) when \( i \geq n' + 1 \). When \( i = n \) or \( i = n' \) then a random decision is required to achieve the error levels \( \mu \) and \( \lambda \) exactly. Formally,

\[
d(\gamma) = \begin{cases} 
(1, 0, 0) & i \leq n - 1 \\
(P_\mu, 1 - P_\mu, 0) & i = n \\
(0, 1, 0) & n < i \leq n' - 1 \\
(0, 1 - P_\lambda, P_\lambda) & i = n' \\
(0, 0, 1) & i \geq n' + 1 
\end{cases} \tag{15}
\]

where \( P_\mu \) and \( P_\lambda \) are defined as the solutions to the equations

\[
u_n \cdot P_\mu = \mu - \sum_{i=1}^{n-1} u_i \tag{16}
\]

\[
m_n \cdot P_\lambda = \lambda - \sum_{i=n'+1}^{N_\Gamma} m_i \tag{17}
\]

**Theorem**: Let \( L_0(\mu, \lambda, \Gamma) \) be the linkage rule defined by (15). Then \( L \) is a best linkage rule on \( \Gamma \) at the levels \( (\mu, \lambda) \). The proof is given in Appendix 1.

The reader will have observed that the whole theory could have been formulated, although somewhat awkwardly, in terms of the classical theory of hypothesis testing. We can test first the null hypothesis that \( (a, b) \in U \) against

\[\text{\footnote{A slightly extended version of the theorem is given in Appendix 1.}}\]
the simple alternative that \((a, b) \in M\), the action \(A_1\) being the rejection of the null hypothesis and \(\mu\) the level of significance. Similarly the action \(A_2\) is the rejection at the significance level \(\lambda\) of the null hypothesis that \((a, b) \in M\) in favour of the simple alternative that \((a, b) \in U\). The linkage rule \(L\) is equivalent to the likelihood ratio test and the theorem above asserts this to be the uniformly most powerful test for either hypothesis.

We state, without proof, two corollaries to the theorem. These corollaries, although mathematically trivial, are important in practice.

**Corollary 1:** If

\[
\mu = \sum_{i=1}^{n} u_i, \quad \lambda = \sum_{i=1}^{n'} m_i, \quad n < n',
\]

the \(L_0(u, \lambda, \Gamma)\), the best linkage rule at the levels \((\mu, \lambda)\) becomes

\[
d(\gamma) = \begin{cases} 
(1, 0, 0) & \text{if } 1 \leq i \leq n \\
(0, 1, 0) & \text{if } n < i < n' \\
(0, 0, 1) & \text{if } n' \leq i \leq N_\Gamma.
\end{cases}
\]  

If we define

\[
T_\mu = \frac{m(\tau_\mu)}{u(\tau_\mu)}
\]

\[
T_\lambda = \frac{m(\tau_\lambda)}{u(\tau_\lambda)}
\]

then the linkage rule (18) can be written equivalently\(^a\) as

\[
d(\gamma) = \begin{cases} 
(1, 0, 0) & \text{if } T_\mu \leq m(\gamma)/u(\gamma) \\
(0, 1, 0) & \text{if } T_\lambda < m(\gamma)/u(\gamma) < T_\mu \\
(0, 0, 1) & \text{if } m(\gamma)/u(\gamma) \leq T_\lambda.
\end{cases}
\]  

**Corollary 2:** Let \(T_\mu\) and \(T_\lambda\) be any two positive numbers such that

\[T_\mu > T_\lambda.\]

Then there exists an admissible pair of error levels \((\mu, \lambda)\) corresponding to \(T_\mu\) and \(T_\lambda\) such that the linkage rule (19) is best at these levels. The levels \((\mu, \lambda)\) are given by

\[
\mu = \sum_{\tau \in \Gamma_\mu} u(\gamma)
\]

\[
\lambda = \sum_{\tau \in \Gamma_\lambda} m(\gamma)
\]

where

\[
\Gamma_\mu = \{ \gamma : T_\mu \leq m(\gamma)/u(\gamma) \}
\]

\[
\Gamma_\lambda = \{ \gamma : m(\gamma)/u(\gamma) \leq T_\lambda \}
\]

\(a\) We are grateful to the referees for pointing out that (19) and (18) are exactly equivalent only if

\[m_{\alpha}/m_{\omega} < m_{\alpha'}/m_{\omega'} \text{ and } m_{\alpha'}/m_{\omega'} < m_{\alpha}/m_{\omega}.\]
In many applications we may be willing to tolerate error levels sufficiently high to preclude the action \( A_2 \). In this case we choose \( n \) and \( n' \) or, alternatively, \( T_2 \) and \( T_1 \) so that the middle set of \( \gamma \) in (18) or (19) is empty. In other words every \((a, b)\) is allocated either to \( M \) or to \( U \). The theory for the allocation of observations to one of two mutually exclusive populations may thus be regarded as a special case of the theory given in this paper.

3. APPLICATIONS

3.1. Some Practical Problems

In attempting to implement the theory developed in the previous section several practical problems need to be solved. They are outlined briefly below and taken up in more detail in subsequent sections.

a) The large number of possible values of \( m(\gamma) \) and \( u(\gamma) \). Clearly the number of distinct realizations of \( \gamma \) may be so large as to make the computation and storage of the corresponding values of \( m(\gamma) \) and \( u(\gamma) \) impractical. The amount of computation and storage can be substantially reduced on the basis of some simplifying assumptions.

b) Methods to calculate the quantities \( m(\gamma) \) and \( u(\gamma) \). Two methods are proposed.

c) Blocking the files. Implicit in the development of the theory is the assumption that if two files are linked then all possible comparisons of all the records of both files will be attempted. It is clear that even for medium sized files the number of comparisons under this assumption would be very large, (e.g. \( 10^6 \) records in each file would imply \( 10^{18} \) comparisons). In practice the files have to be “blocked” in some fashion and comparisons made only within corresponding blocks. The impact of such blocking on the error levels will be examined.

d) Calculations of threshold values. It should be clear from Corollary 2 that we do not have to order explicitly the values of \( \gamma \) in order to apply the main theorem since for any particular \( \gamma \) the appropriate decision \( (A_1, A_2 \text{ or } A_3) \) can be made by comparing \( m(\gamma)/u(\gamma) \) with the threshold values \( T_1 \) and \( T_2 \). We shall outline a method of establishing these threshold values corresponding to the required error levels \( \mu \) and \( \lambda \).

e) Choice of the comparison space. The main theorem provides an optimal linkage rule for a given comparison space. Some guidance will be provided on the choice of the comparison space.

3.2. Some simplifying assumptions

In practice the set of distinct (vector) values of \( \gamma \) may be so large that the estimation of the corresponding probabilities \( m(\gamma) \) and \( u(\gamma) \) becomes completely impracticable. In order to make use of the theorem it will be necessary to make some simplifying assumptions about the distribution of \( \gamma \).

We assume that the components of \( \gamma \) can be re-ordered and grouped in such a way that

\[ \gamma = (\gamma^1, \gamma^2, \cdots, \gamma^n) \]

and that the (vector) components are mutually statistically independent with
respect to each of the conditional distributions. Thus
\[ m(\gamma) = m_1(\gamma^1) \cdot m_2(\gamma^2) \cdots m_K(\gamma^K) \]  
\[ u(\gamma) = u_1(\gamma^1) \cdot u_2(\gamma^2) \cdots u_K(\gamma^K) \]

where \( m(\gamma) \) and \( u(\gamma) \) are defined by (4) and (5) respectively and
\[ m_i(\gamma^i) = P(\gamma^i \mid (a, b) \in M) \]
\[ u_i(\gamma^i) = P(\gamma^i \mid (a, b) \in U). \]

For simplicity of notation we shall write \( m(\gamma) \) and \( u(\gamma) \) instead of the technically more precise \( m_i(\gamma^i) \) and \( u_i(\gamma^i) \). As an example, in a comparison of records relating to persons \( \gamma^1 \) might include all comparison components that relate to surnames, \( \gamma^2 \) all comparison components that relate to addresses. The components \( \gamma^1 \) and \( \gamma^2 \) are themselves vectors; the subcomponents of \( \gamma^2 \) for example might represent the coded results of comparing the different components of the address (city name, street name, house number, etc.). If two records are matched (i.e. when in fact they represent the same person or event), then a disagreement configuration could occur due to errors. Our assumption says that errors in names, for example, are independent of errors in addresses. If two records are unmatched (i.e. when in fact they represent different persons or events) then our assumption says that an accidental agreement on name, for example, is independent of an accidental agreement on address. In other words what we do assume is that \( \gamma^1, \gamma^2, \ldots, \gamma^K \) are conditionally independently distributed. We emphasize that we do not assume anything about the unconditional distribution of \( \gamma \).

It is clear that any monotone increasing function of \( m(\gamma)/u(\gamma) \) could serve equally well as a test statistic for the purpose of our linkage rule. In particular it will be advantageous to use the logarithm of this ratio and define
\[ w^k(\gamma^k) = \log m(\gamma^k) - \log u(\gamma^k). \]  

We can then write
\[ w(\gamma) = w^1 + w^2 + \cdots + w^K \]
and use \( w(\gamma) \) as our test statistic with the understanding that if \( u(\gamma) = 0 \) or \( m(\gamma) = 0 \) then \( w(\gamma) = +\infty \) (or \( w(\gamma) = -\infty \)) in the sense that \( w(\gamma) \) is greater (or smaller) than any given finite number.

Suppose that \( \gamma^k \) can take on \( n_k \) different configurations, \( \gamma^k_1, \gamma^k_2, \ldots, \gamma^k_{n_k} \). We define
\[ w^k_i = \log m(\gamma^k_i) - \log u(\gamma^k_i). \]  

It is a convenience for the intuitive interpretation of the linkage process that the weights so defined are positive for those configurations for which \( m(\gamma^k_i) > u(\gamma^k_i) \), negative for those configurations for which \( m(\gamma^k_i) < u(\gamma^k_i) \), and that this property is preserved by the weights associated with the total configuration \( \gamma \).

The number of total configurations (i.e. the number of points \( \gamma \in \Gamma \)) is obviously \( n_1 \cdot n_2 \cdots n_K \). However, because of the additive property of the
weights defined for components it will be sufficient to determine $n_1 + n_2 + \cdots + n_K$ weights. We can then always determine the weight associated with any $\gamma$ by employing this additivity.

3.3. The Calculation of Weights

An assumption made at the outset of this paper was that the files $L_A$ and $L_B$ represent samples $A_1$ and $B_1$ of the populations $A$ and $B$. This assumption is often necessary in some applications when one wishes to use a set of values of $m(\gamma^4)$ and $u(\gamma^4)$, computed for some large populations $A$ and $B$ while the actually observed files $L_A$ and $L_B$ correspond to some subpopulations $A_1$ and $B_1$. For example, in comparing a set of incoming records against a master file in order to update the file one may want to consider the master file and the incoming set of records as corresponding to samples $A_1$ and $B_1$ of some conceptual populations $A$ and $B$. One might compute the weights for the full comparison space $\Gamma$ corresponding to $A$ and $B$ and apply these weights repeatedly on different update runs; otherwise one would have to recompute the weights on each occasion.

Of course it seldom occurs in practice that the subpopulations represented by the files $L_A$ and $L_B$ are actually drawn at random from any real populations $A$ and $B$. However it is clear that all the theory presented in this paper will still hold if the assumption is relaxed to the assumption that the condition of entry of the subpopulation into the files is uncorrelated with the distribution in the populations of the characteristics used for comparisons. This second assumption obviously holds if the first does, although the converse is not necessarily true.

In this paper we propose two methods for calculating weights. In the first of these we assume that prior information is available on the distribution in the populations $A$ and $B$ of the characteristics used in comparison as well as on the probabilities of different types of error introduced into the files by the record generating processes. The second method utilizes the information in the files $L_A$ and $L_B$ themselves to estimate the probabilities $m(\gamma^4)$ and $u(\gamma^4)$. The validity of these estimates is strongly predicated on the independence assumption of the previous section. Specifically it requires that the formal expression for that independence should hold almost exactly in the subpopulation $L_A \times L_B$, which, in turn, requires that the files $L_A$ and $L_B$ should be large and should satisfy at least the weaker of the assumptions of the previous paragraph.

Another procedure, proposed by Tepping ([11], [13]), is to draw a sample from $L_A \times L_B$, identify somehow (with negligible error) the matched and unmatched comparisons in this sample, and thus estimate $m(\gamma)$ and $u(\gamma)$ directly. The procedure seems to have some difficulties associated with it. If and when the identification of matched and unmatched records can in fact be carried out with reasonable accuracy and with reasonable economy (even if only at least occasionally) then it might provide a useful check or corroboration of the reasonableness of assumptions underlying the calculation of weights.

Finally, the weights $w(\gamma)$ or alternatively the probabilities $m(\gamma)$ and $u(\gamma)$, derived on one occasion for the linkage $L_A \times L_B$ can continue to be used on a
subsequent occasion for the linkage, say $L_A' \times L_B'$, provided $A$ and $B$, can be regarded as samples from the same populations as $A$, and $B$, and provided the record generating processes are unaltered.

3.3.1. Method I

Suppose that one component of the records associated with each of the two populations $A$ and $B$ is the surname. The comparison of surnames on two records will result in a component of the comparison vector. This component may be a simple comparison component such as “name agrees” or “name disagrees” or “name missing on one or both records” (in this case $\gamma$ is a scalar); or it may be a more complicated vector component such as for example “records agree on Soundex code, the Soundex code is B650; the first 5 characters of the name agree; the second 5 characters of the name agree; the surname is BROWNING.”

In either of the two files the surname may be reported in error. Assume that we could list all error-free realizations of all surnames in the two populations and also the number of individuals in the respective populations corresponding to each of these surnames. Let the respective frequencies in $A$ and $B$ be

$$f_{A1}, f_{A2}, \ldots, f_{An}; \quad \sum_{i=1}^{m} f_{Ai} = N_A$$

and

$$f_{B1}, f_{B2}, \ldots, f_{Bn}; \quad \sum_{j=1}^{m} f_{Bj} = N_B.$$ 

Let the corresponding frequencies in $A \cap B$ be

$$f_1, f_2, \ldots, f_m; \quad \sum_{j} f_j = N_{AB}.$$ 

The following additional notation is needed:

- $e_A$ or $e_B$ the respective probabilities of a name being misreported in $L_A$ or $L_B$ (we assume that the probability of misreporting is independent of the particular name);
- $e_{A0}$ or $e_{B0}$ the respective probabilities of a name not being reported in $L_A$ or $L_B$ (we assume that the probability of name not being reported is independent of the particular name);
- $e_T$ the probability the name of a person is differently (though correctly) reported in the two files (this might arise, for example, if $L_A$ and $L_B$ were generated at different times and the person changed his name).

Finally we assume that $e_A$ and $e_B$ are sufficiently small that the probability of an agreement on two identical, though erroneous, entries is negligible and that the probabilities of misreporting, not reporting and change are independent of one another.

We shall first give a few rules for the calculation of $m$ and $u$ corresponding...
to the following configurations of \( \gamma \): name agrees and it is the \( j \)th listed name, name disagrees; name missing on either record.

\[ m \text{ (name agrees and is the } j \text{th listed name)} \]
\[ = \frac{f_j}{N_{AB}} (1 - e_A)(1 - e_B)(1 - e_T)(1 - e_{A0})(1 - e_{B0}) \]  
\[ = \frac{f_j}{N_{AB}} (1 - e_A - e_B - e_T - e_{A0} - e_{B0}) \]  

(29)

\[ m \text{ (name disagrees)} \]
\[ = [1 - (1 - e_A)(1 - e_B)(1 - e_T)](1 - e_{A0})(1 - e_{B0}) \]
\[ = e_A + e_B + e_T \]  

(30)

\[ m \text{ (name missing on either file)} \]
\[ = 1 - (1 - e_{A0})(1 - e_{B0}) \]
\[ = e_{A0} + e_{B0} \]  

(31)

\[ u \text{ (name agrees and is the } j \text{th listed name)} \]
\[ = \frac{f_{Aj}}{N_A} \frac{f_{Bj}}{N_B} (1 - e_A)(1 - e_T)(1 - e_{A0})(1 - e_{B0}) \]
\[ = \frac{f_{Aj}}{N_A} \frac{f_{Bj}}{N_B} (1 - e_A - e_B - e_T - e_{A0} - e_{B0}) \]  

(32)

\[ u \text{ (name disagrees)} \]
\[ = \left[ 1 - (1 - e_A)(1 - e_B)(1 - e_T) \sum_j \frac{f_{Aj}}{N_A} \frac{f_{Bj}}{N_B} \right](1 - e_{A0})(1 - e_{B0}) \]
\[ = \left[ 1 - (1 - e_A - e_B - e_T) \sum_j \frac{f_{Aj}}{N_A} \frac{f_{Bj}}{N_B} \right](1 - e_{A0} - e_{B0}) \]  

(33)

\[ u \text{ (name missing on either file)} \]
\[ = 1 - (1 - e_{A0})(1 - e_{B0}) \]
\[ = e_{A0} + e_{B0}. \]  

(34)

The proportions \( f_{Aj}/N_A, f_{Bj}/N_B, f_j/N \) may be taken, in many applications, to be the same. This would be the case, for example, if two large files can be assumed to be drawn from the same population. These frequencies may be estimated from the files themselves.

A second remark relates to the interpretation of weights. It will be recalled that according to (28) the contribution to the overall weight of the name component is equal to \( \log (m/u) \) and that comparisons with a weight higher than a specified number will be considered linked, while those whose weight is below a specified number will be considered unlinked. It is clear from (29–34) that an agreement on name will produce a positive weight and in fact the rarer the name, the larger the weight; a disagreement on name will produce a negative weight which decreases with the errors \( e_A, e_B, e_T \); if the name is missing on either record, the weight will be zero. These results seem intuitively appealing.
We should emphasize that it is not necessary to list all possible names for the validity of formulae (29) to (34). We might only list the more common names separately, grouping all the remaining names. In the case of groupings the appropriate formulae in (29) to (34) have to be summed over the corresponding values of the subscript $j$. The problem of how to group configurations is taken up in a later section.

Finally we should mention that formulae (29) to (34) relate to reasonably simple realizations of $\gamma$, such as a list of names, or list of ages, or lists of other possible identifiers. In more complex cases one may be able to make use of these results, with appropriate modifications, in conjunction with the elementary rules of probability calculus. Alternatively one may have recourse to the method given below.

### 3.3.2. Method II

The formulae presented in Appendix 2 can be used, under certain circumstances, to estimate the quantities $m(\gamma^h)$, $u(\gamma^h)$ and $N$, the number of matched records, simply by substituting into these formulae certain frequencies which can be directly (and automatically) counted by comparing the two files. Mathematically, the only condition for the validity of these formulae is that $\gamma$ should have at least three components which are independent with respect to the probability measures $m$ and $u$ in the sense of (24) and (25). It should be kept in mind, however, that for agreement configurations $m(\gamma^h)$ is typically very close to one, $u(\gamma^h)$ is very close to zero, and conversely for disagreement configurations. Therefore the estimates of $u(\gamma^h)$ and $m(\gamma^h)$ can be subject to substantial sampling variability unless the two files represent censuses or large random samples of the populations $A$ and $B$.

The detailed formulae and their proofs are included in the Appendix. At this point only an indication of the methods will be given. For simplicity we present the method in terms of three components. If, in fact, there are more than three components they can be grouped until there are only three left. Clearly this can be done without violating (24) and (25).

For each component vector of $\gamma$ designate the set of configurations to be considered as “agreements” and denote this set (of vectors) for the $h$th component by $S_h$. The designation of specific configurations as “agreements” may be arbitrary but subject to some numerical considerations to be outlined in the Appendix.

The following notation refers to the frequencies of various configurations of $\gamma$. Since they are not conditional frequencies, they can be obtained as direct counts by comparing the files $L_A$ and $L_B$:

- $M_h$: the proportion of “agreement” in all components except the $h$th; any configuration in the $k$th component;
- $U_k$: the proportion of “agreement” in the $h$th component; any configuration in the others;
- $M$: the proportion of “agreement” in all components.

Denote also the respective conditional probabilities of “agreements” by...
\[
m_h = \sum_{\gamma \in S_A} m(\gamma) \tag{35}
\]

\[
u_h = \sum_{\gamma \in S_A} u(\gamma). \tag{36}
\]

It follows from the assumptions (24) and (25) that the expected values of \( M_h, U_h, \) and \( M \) with respect to the sampling procedure (if any) and the record generating process through which the files \( L_A \) and \( L_B \) arose from the populations \( A \) and \( B \) can be expressed simply in terms of \( m_h \) and \( u_h \) as follows.

\[
N_A N_B E(M_h) = E(N) \sum_{j=1}^{3} m_j + [N_A N_B - E(N)] \sum_{j=1}^{3} u_j; \quad h = 1, 2, 3 \tag{37}
\]

\[
N_A N_B E(U_h) = E(N) m_h + [N_A N_B - E(N)] u_h \tag{38}
\]

\[
N_A N_B E(M) = E(N) \sum_{j=1}^{3} m_j + [N_A N_B - E(N)] \sum_{j=1}^{3} u_j \tag{39}
\]

where \( N_A \) and \( N_B \) are the known number of records in the files \( L_A \) and \( L_B \) and \( N \) is the unknown number of matched records.

Dropping the expected values we obtain seven equations for the estimation of the seven unknown quantities \( N, m_h, u_h (h = 1, 2, 3) \). The solution of these equations is given in Appendix 2.

Having solved for \( m_h, u_h \) and \( N \) the quantities \( m(\gamma^*) \) and \( u(\gamma^*) \) are easily computed by substituting some additional directly observable frequencies into some other equations, also presented in Appendix 2. The frequency counts required for all the calculations can be obtained at the price of three sorts of the two files.

It is our duty to warn the reader again that although these equations provide statistically consistent estimates, the sampling variability of the estimates may be considerable if the number of records involved \( (N_A N_B) \) is not sufficiently large. One might get an impression of the sampling variabilities through the method of random replication, i.e., by splitting both of the files at random into at least two parts and by performing the estimation separately for each. Alternatively, one can at least get an impression of the sampling variabilities of \( M_h, U_h \) and \( M \) by assuming that they are estimated from a random sample of size \( N_A N_B \).

Another word of caution may be in order. The estimates are computed on the basis of the independence assumptions of (24) and (25). In the case of departures from independence the estimates, as estimates of the probabilities \( m(\gamma^*) \) and \( u(\gamma^*) \), may be seriously affected and the resulting weights \( m(\gamma^*)/u(\gamma^*) \) would lose their probabilistic interpretations. What is important, of course, is their effect on the resulting linkage operation. We believe that if sufficient identifying information is available in the two files to carry out the linkage operation in the first place, then the operation is quite robust against departures from independence. One can get an impression of the extent of the departures from independence by carrying out the calculations of Appendix 2 on the basis of alternative designations of the "agreement" configurations.
3.4. Restriction of Explicit Comparisons to a Subspace

In practice of course we do not select comparisons at random from \( L_A \times L_B \). But then in practice we are not concerned with the probability of the event \((A_1 \cup U)\) or the event \((A_3 | M)\) for any particular comparison but rather with the proportion of occurrences of these two events in the long run. Clearly if our linkage procedure is to examine every comparison \((a, \beta) \in L_A \times L_B\) then we could formally treat any particular comparison as if it had been drawn at random from \( L_A \times L_B \). The only change in our theory in this case would be the replacement of probabilities with proportions. In particular the probabilities of error \( \mu \) and \( \lambda \) would then have to be interpreted as proportions of errors. With this understanding we can continue to use the notation and concepts of probability calculus in this paper even though often we shall think of probabilities as proportions.

We have now made explicit a second point which needs to be examined. We would seldom be prepared to examine every \((a, \beta) \in L_A \times L_B\) since it is clear that even for medium sized files (say \( 10^5 \) record each) the number of comparisons \( 10^{10} \) would outstrip the economic capacity of even the largest and fastest computers.

Thus the number of comparisons we will examine explicitly will be restricted to a subspace, say \( \Gamma^* \), of \( \Gamma \). This might be achieved for example by partitioning or “blocking” the two files into Soundex-coded Surname “blocks” and making explicit comparisons only between records in corresponding blocks. The subspace \( \Gamma^* \) is then the set of \( \gamma \) for which the Soundex Surname component has the agreement status. All other \( \gamma \) are implicit positive non-links (the comparisons in \( \Gamma \setminus \Gamma^* \) will not even be actually compared hence they may not be either positive or possible links). We consider the effect that this procedure has on the error levels established for the all-comparison procedure.

Let \( \Gamma_u \) be established (as in Corollary 2) for the all-comparison procedure so as to satisfy

\[
\Gamma_u = \{ \gamma : T_u \leq m(\gamma)/u(\gamma) \}
\]

where

\[
\mu = \sum_{\gamma \in \Gamma_u} u(\gamma)
\]

\[
\lambda = \sum_{\gamma \in \Gamma_u} m(\gamma).
\]

If we now regard all \( \gamma \in (\Gamma \setminus \Gamma^*) \) as implicit positive non-links we must adjust our error levels to

\[
\mu^* = \mu - \sum_{\gamma \in (\Gamma \setminus \Gamma^*)} u(\gamma) \quad (40)
\]

\[
\lambda^* = \lambda + \sum_{\gamma \in (\Gamma \setminus \Gamma^*)} m(\gamma) \quad (41)
\]

where \( \Gamma^*_u \) and \( \Gamma^*_u \) denote complements taken with respect to \( \Gamma \) (i.e. \( \Gamma \setminus \Gamma_u \) and \( \Gamma \setminus \Gamma^*_u \), respectively).
The first of these expressions indicates that the level of $\mu$ is reduced by the sum of the $u$-probabilities of those comparisons which would have been links under the all-comparison procedure but are implicit non-links under the blocking procedure. The second expression indicates that the actual level of $\lambda$ is increased by the sum of the $m$-probabilities of the comparisons that would be links or possible links under the all-comparison procedure but are implicit non-links under the blocking procedure.

The probabilities of a failure to make a positive disposition under the blocking procedure are given by

$$P^*(A_1 \mid M) = \sum_{\gamma \in \mathbb{M} \cap \mathbb{F}} m(\gamma) - \sum_{\gamma \in \mathbb{M} \cap \mathbb{F} \cap \mathbb{F}^*} m(\gamma)$$

$$P^*(A_1 \mid U) = \sum_{\gamma \in \mathbb{F} \cap \mathbb{F}^*} u(\gamma) - \sum_{\gamma \in \mathbb{M} \cap \mathbb{F} \cap \mathbb{F}^*} u(\gamma)$$

the second term on the right in each case being the reduction due to the blocking procedure.

These expressions will be found to be useful when we consider the best way of blocking a file.

### 3.5. Choice of Error Levels and Choice of Subspace

In choosing the error levels $(\mu, \lambda)$ we may want to be guided by the consideration of losses incurred by the different actions.

Let $G_M(A_i)$ and $G_U(A_i)$ be non-negative loss functions which give the loss associated with the disposition $A_i$; $(i = 1, 2, 3);$ for each type of comparison. Normally, we would set

$$G_M(A_1) = G_U(A_3) = 0$$

and we do so here. Reverting to the all-comparison procedure we set $(\mu, \lambda)$ so as to minimize the expected loss given by the expression

$$P(M) \cdot E[G_M(A_1)] + P(U) \cdot E[G_U(A_1)]$$

$$= P(M) \left[ P(A_1 \mid M) \cdot G_M(A_1) + \lambda \cdot G_M(A_3) \right] + P(U) \left[ u \cdot G_U(A_1) + P(A_1 \mid U) \cdot G_U(A_3) \right]$$

(44)

Note that $P(A_1 \mid M)$ and $P(A_1 \mid U)$ are functions of $\mu$ and $\lambda$. We give later a practical procedure for determining the values of $(\mu, \lambda)$ which minimize (44).

Suppose that $(\mu, \lambda)$ have been set so as to minimize (44). We now consider the effects of blocking the files and introduce an additional component in the loss function which expresses the costs of comparisons, $G_{\Gamma^*}(L_A \times L_B)$, under a blocking procedure equivalent to making implicit comparisons in a subspace $\Gamma^*$. We seek that subspace $\Gamma^*$ which minimizes the total expected loss,

$$c \{ P(M) \cdot E[G_M(A_1)] + P(U) \cdot E[G_U(A_1)] \}
+ G_{\Gamma^*}(L_A \times L_B)
= c \{ P(M) \left[ P^*(A_1 \mid M) G_M(A_1) + \lambda^* G_M(A_3) \right] + P(U) \left[ u^* G_U(A_1) + P^*(A_1 \mid U) G_U(A_3) \right] \}
+ G_{\Gamma^*}(L_A \times L_B)$$

(45)
where \( P^* \) denotes probabilities under the blocking procedure given by (42) and (43) respectively and \( c \) denotes the number of comparisons in \( L_A \times L_B \). Now if the processing cost of comparisons under any blocking \( \Gamma^* \) is simply proportional to the number of comparisons, \( c^* \), i.e.

\[
G_{\Gamma^*}(L_A \times L_B) = ac^*
\]

then we can minimize

\[
P(M) [P^*(A_1 | M) G_M(A_2) + P^*(A_2 | M) G_M(A_1)] + P(U) [\mu^* G_U(A_1) + P^*(A_1 | U) G_U(A_2)] + \frac{ac^*}{c}.
\]

The last term is the product of the cost, \( a \), per comparison and the reduction ratio in the number of comparisons to be made explicitly.

No explicit solution of (46) seems possible under such general conditions. However, (46) can be used to compare two different choices of \( \Gamma^* \). Once a choice of \( \Gamma^* \) has been made, the “theoretical” error levels \( \mu, \lambda \) can be chosen, using (40) and (41), so that the actual error levels \( \mu^*, \lambda^* \) meet the error specification. The threshold values \( T_\mu, T_\lambda \) are then calculated from the “theoretical” error levels.

### 3.6. Choice of comparison space

Let \( \Gamma \) and \( \Gamma' \) be two comparison spaces, with conditional distributions \( m(w) \), \( u(w) \) and \( m'(w) \), \( u'(w) \) and threshold values \( T_\mu, T_\lambda \) and \( T'_\mu, T'_\lambda \) respectively (the threshold values being in both cases so determined that they lead to the same error levels \( \mu, \lambda \)).

Now in a manner precisely analogous to our linkage criterion we might say that a comparison space \( \Gamma \) is better than a comparison space \( \Gamma' \) at the error levels \( (\mu, \lambda) \) if

\[
P(T_\mu < w(\gamma) < T_\mu') < P(T'_\mu < w'(\gamma') < T'_\mu')
\]

where it is assumed that the comparisons are made under the optimal linkage rule in each case. The linkage criterion developed for a given \( \Gamma \) is independent of \( (\mu, \lambda) \) and \( P(M) \). Clearly we cannot hope for this to be the case in general with a criterion for the choice of a comparison space.

Expanding the expression (47) we have as our criterion at the level \( (\mu, \lambda) \)

\[
P(M) \cdot \sum_{T_\mu < w < T_\mu'} m(w) + P(U) \cdot \sum_{T_\lambda < w < T_\lambda'} u(w)
\]

\[
< P(M) \cdot \sum_{T_\mu < w < T_\mu'} m'(w) + P(U) \cdot \sum_{T_\lambda < w < T_\lambda'} u'(w) \quad (48)
\]

In most practical cases of course \( P(M) \) is very small and the two sides of (48) are dominated by the second term. However if a “blocking” procedure has reduced the number of unmatched comparisons greatly it would be more appropriate to use \( P^*(M) \) and \( P^*(U) \) appropriate to the subspace \( \Gamma^* \) (i.e. to the set of comparisons that will be made explicitly), than to use \( P(M) \) and \( P(U) \) provided the same “blocking” procedure is to be used for each choice of comparison space. \( P(M) \) and \( P(U) \), or alternatively \( P^*(M) \) and \( P^*(U) \), have to be
guessed at for the application of (48). The difference between the right hand
side and the left hand side of (48) is equal to the reduction of \( P(A) \) due to the
choice of the comparison space.

In practice the difference between two comparison spaces will often be the
number of configurations of component vectors which are listed out in addition
to the simple "agreement"—"disagreement" configurations (e.g. "agreement
on name Jones," "agreement on name Smith," etc.). The formula (48) can be
used to compare the loss or gain in dropping some special configurations or
listing out explicitly some more.

3.7. Calculation of threshold values

Having specified all the relevant configurations \( \gamma^k \) and determined their
associated weights \( w^k \); \( k = 1, 2, \cdots, K \); \( j = 1, 2, \cdots, n_k \) it remains to set the
threshold values \( T_\mu \) and \( T_\lambda \) corresponding to given \( \mu \) and \( \lambda \) and to estimate the
number or proportion of failures to make positive dispositions of comparisons.

As shown before, the number of weights to be determined is equal to
\( n_1 + n_2 + \cdots + n_K \). The total number of different configurations is, however,
\( n_1 n_2 \cdots n_K \). Since the number of total configurations will, in most practical
situations, be too large for their complete listing and ordering to be feasible
we have resorted to sampling the configurations in order to estimate \( T_\mu \) and \( T_\lambda \).
Since we are primarily interested in the two ends of an ordered list of total
configurations we sample with relatively high probabilities for configurations
which have very high or very low weights \( w^k \).

The problem is made considerably easier by the independence of the com-
ponent vectors \( \gamma^k \). Thus if we sample independently the component configu-
rations \( \gamma^k_1, \gamma^k_2, \cdots, \gamma^k_K \) with probabilities \( z^k_1, z^k_2, \cdots, z^k_K \) respectively we will
have sampled the total configuration \( \gamma = (\gamma^k_1, \gamma^k_2, \cdots, \gamma^k_K) \) with probability
\( z_k = z^k_1 z^k_2 \cdots z^k_K \). Hence we do not need to list all configurations of \( \gamma \) for
sampling purposes, only all configurations of \( \gamma^k \) for each \( k \).

We speed up the sampling process and increase the efficiency of the sample
by ordering the configurations listed for each component by decreasing values
\( w^k \), and sampling according to the following scheme:

1) Assign selection probabilities \( \bar{z}^k_1, \bar{z}^k_2, \cdots, \bar{z}^k_n \) roughly proportional to \( \left| w^k \right| \).
2) Choose a configuration from each component. If the configuration \( \gamma^k_j \)
is chosen from the \( k \)th component (with probability \( \bar{z}^k_j \)) choose also the
configuration \( \gamma^k_{n_j - m} \).
3) Combine the first members of the pairs chosen from each component to
give one total configuration and the second members to give another.
4) Repeat the whole procedure \( S/2 \) times to give a with-replacement sample
of \( S \) total configurations.

The sample is then ordered by decreasing values of
\[
    w = w_1 + w_2 + \cdots + w_K.
\] (49)

Let \( \gamma(k = 1, 2, \cdots, S) \) be the \( k \)th member of the ordered listing of the sample.
(Note: If a configuration with the same value of \( w \) occurs twice in the sample,
it is listed twice.) Then \( P(w(\gamma) < w(\gamma_k)| \gamma \in M) \) is estimated by
where 
\[ \lambda_h = \sum_{h'=h}^{S} m(\gamma_{h'})/\pi(\gamma_{h'}) \]  
(50)

\[ \pi(\gamma_h) = \frac{S}{2} \cdot z'(\gamma_h) \]  
(51)

and
\[ z'(\gamma_h) = z_h z_2 \cdots z_K + z_{h-1} z_{h+1} \cdots z_K \]  
(52)

while
\[ P'(w(\gamma) < w(\gamma_h) \mid \gamma \in U) \]  
is estimated by
\[ \mu_h = \sum_{h'=1}^{h} u(\gamma_{h'})/\pi(\gamma_{h'}). \]  
(53)

The threshold values \( T(\lambda_h) \) and \( T(\mu_h) \), are simply the weights \( w(\gamma_{h'}) \) and \( w(\gamma_{h'}). \)

We have written a computer program which, working from a list of configurations for each vector component and associated selection probabilities, selects a sample of total configurations, orders the sample according to (49), calculates the estimates (50) and (53) and finally prints out the whole list giving for each total configuration its associated \( \lambda_h, \mu_h, T(\lambda_h), \) and \( T(\mu_h). \)

We can use the same program to examine alternative blocking procedures (see Section 3.4). Thus in the ordered listing of sampled configurations we can identify those which would be implicit positive non-links under a blocking procedure which restricts explicit comparisons to a subspace \( \Gamma^* \). Thus corresponding to any values of \( T_\mu \) and \( T_\lambda \) (or \( \mu \) and \( \lambda \)) we can obtain the second terms in each of the expressions (40), (41), (42), and (43). Alternatively if the implicit positive non-links are passed over in the summations (40) and (41) we can read off the values of the left-hand sides of those expressions. If we arrange this for alternative blocking procedures we are able to use the output of the program to make a choice of blocking procedures according to (46).

4. ACKNOWLEDGMENTS

The authors would like to express their gratitude to the Dominion Bureau of Statistics for providing opportunities for this research and in particular to Dr. S. A. Goldberg for his continued support.

The authors would also like to express their appreciation to H. B. Newcombe for his pioneering work in the field of record linkage and for his generous encouragement of an approach which, in many respects, differs from his own. The contributions of J. N. Gauthier, the systems analyst in charge of programming for our pilot project, have been essential to whatever success we have enjoyed so far and will continue to be essential in what remains for us to do.

REFERENCES

A FUNDAMENTAL THEOREM FOR RECORD LINKAGE

We stated that \((\mu, \lambda)\) is an admissible pair of error levels provided \(\mu\) and \(\lambda\) are not both too large. We will make this statement more precise.

Let

\[
U_n = \sum_{i=1}^{n} u_i; \quad n = 1, 2, \ldots, N_f
\]

\[
U_0 = 0
\]

\[
M_{n'} = \sum_{i=n'}^{N_f} m_i; \quad n' = 1, 2, \ldots, N_f
\]

\[
M_{N_f+1} = 0
\]

and define \(f(\mu)\), as shown in Figure 1, on the interval \((0, 1)\) as the monotone decreasing polygon line passing through the points \((U_n, M_{n+1})\) for \(n=0, 1, \ldots, N_f\). It is possible of course to state the definition more precisely, but unnecessary for our purposes.

The area contained by the axes and including the line \(\lambda = f(\mu)\) defines the region of admissible pairs \((\mu, \lambda)\). In other words \((\mu, \lambda)\) is an admissible pair if
Fig. 1

\[ 0 < \lambda \leq f(\mu) \]

and \[ 0 < \mu. \] (5)

Let \( n(\mu) \) be the integer such that

\[ U_{n(\mu) - 1} < \mu \leq U_{n(\mu)} \] (6)

and \( n'(\lambda) \) the integer such that

\[ M_{n'(\lambda)} \geq \lambda > M_{n'(\lambda) + 1}. \] (7)

Define

\[ P_\lambda = \frac{\lambda - M_{n'(\lambda) + 1}}{m_{n'(\lambda)}} \] (8)
and
\[ P_\ast = \frac{\mu - U_{n(\mu) - 1}}{U_{n(\mu)}}. \] (9)

It follows from the way in which the configurations were ordered and the restrictions on \( \mu \) and \( \lambda \) that the denominators of the expressions on the right of (8) and (9) are positive.

It is easy to see from Figure 1 that
\[ 0 < P_\lambda \leq 1 \quad \text{and} \quad 0 < P_\ast \leq 1. \] (10)

It is also clear from Figure 1 that \((\mu, \lambda)\) are admissible if and only if
(a) \( n'(\lambda) \geq n(\mu) + 1 \)
\((e.g. (\mu_a, \lambda_a) \text{ in Figure 1})\)
or
(b) \( n'(\lambda) = n(\mu) \) and \( P_\lambda + P_\ast \leq 1 \)
\((e.g. (\mu_b, \lambda_b) \text{ in Figure 1}).\)

Thus (a) and (b) simply divide the admissible region into two areas, one bounded by the axes and the broken lines in Figure 1, and the other bounded by the broken lines and the polygon line \( \lambda = f(\mu) \).

Finally, from Figure 1 and the definitions of \( n(\mu) \) and \( n'(\lambda) \) we see that \( \lambda = f(\mu) \) if and only if
(a) \( n'(\lambda) = n(\mu) + 1 \) and \( P_\lambda = P_\ast \)
\((i.e. \text{ the vertices of } \lambda = f(\mu)).\)
or
(b) \( n'(\lambda) = n(\mu) \) and \( P_\lambda + P_\ast = 1 \)
\((i.e. \text{ points on } \lambda = f(\mu) \text{ other than vertices}).\)

Let \((\mu, \lambda)\) be an admissible pair of error levels on \( \Gamma \). We define a linkage rule \( L_0(\mu, \lambda, \Gamma) \) as follows:
1) If \( n'(\lambda) > n(\mu) + 1 \) then
\[ d_{0}(\gamma_i) = \begin{cases} 
(1, 0, 0) & \text{if } i \leq n(\mu) - 1 \\
(P_\mu, 1 - P_\mu, 0) & \text{if } i = n(\mu) \\
(0, 1, 0) & \text{if } n(\mu) + 1 \leq i \leq n'(\lambda) - 1 \\
(0, 1 - P_\lambda, P_\lambda) & \text{if } i = n'(\lambda) \\
(0, 0, 1) & \text{if } i \geq n'(\lambda) + 1
\end{cases} \]
2) If \( n'(\lambda) = n(\mu) \) and \( P_\lambda + P_\ast \leq 1 \)
\[ d_{0}(\gamma_i) = \begin{cases} 
(1, 0, 0) & \text{if } i \leq n(\mu) - 1 \\
(P_\mu, 1 - P_\mu - P_\lambda, P_\lambda) & \text{if } i = n(\mu) = n'(\lambda) \\
(0, 0, 1) & \text{if } i \geq n'(\lambda) + 1.
\end{cases} \]
It is easy to see that \((\mu, \lambda)\) is admissible if and only if one of the two conditions above holds.

We have now defined a linkage rule for an arbitrary pair of admissible levels \((\mu, \lambda)\). It follows immediately from the definition of \(L_0(\mu, \lambda, \Gamma)\) that \(P(A_2) = 0\) if and only if \(\lambda = f(\mu)\).

**Theorem:** If \((\mu, \lambda)\) is an admissible pair of error levels on \(\Gamma\) then \(L_0(\mu, \lambda, \Gamma)\) is the best linkage rule on \(\Gamma\) at the levels \(\mu\) and \(\lambda\). If \((\mu, \lambda)\) is not admissible on \(\Gamma\) then there are levels \((\mu_0, \lambda_0)\) with

\[
\mu_0 \leq \mu, \quad \text{and} \quad \lambda_0 \leq \lambda
\]  

(with at least one of the inequalities in (14) being a definite inequality) such that \(L_0(\mu_0, \lambda_0, \Gamma)\) is better than \(L_0(\mu, \lambda, \Gamma)\) and for which

\[
P_{L_0}(A_2) = 0.
\]  

This theorem explains the terminology “inadmissible.” This simply means that we should not consider linkage rules at inadmissible error levels, since in this case \(L_0^*\) always provides a linkage rule at lower error levels for which we still have \(P(A_2) = 0\) (i.e., only the positive dispositions \(A_1\) and \(A_2\) occur).

**Proof:**

Let \(L'(\mu, \lambda, \Gamma)\) be any linkage rule with admissible levels \((\mu, \lambda)\). Then \(L'(\mu, \lambda, \Gamma)\) can be characterized by the set of decision functions

\[
d'(\gamma_i) = (P'_{i1}, P'_{i2}, P'_{i3}), \quad \sum_{j=1}^{N_{\gamma}} P'_{ij} = 1 \quad i = 1, 2, \ldots, N_{\gamma}
\]  

where

\[
P'_{ij} = P(A_j | \gamma_i), \quad j = 1, 2, 3; \quad i = 1, 2, \ldots, N_{\gamma}.
\]  

Clearly

\[
P_{L'}(A_1 | L') = \sum_{i=1}^{N_{\gamma}} u_i P'_{i1} = \mu
\]  

\[
P_{L'}(A_1 | M) = \sum_{i=1}^{N_{\gamma}} m_i P'_{i3} = \lambda.
\]  

Consider the linkage rule \(L_0(\mu, \lambda, \Gamma)\). It is characterized by equations analogous to (16) to (19) but \(P'_{ij}\) replaced by \(P_{ij}\) as defined above. We shall prove that

\[
P(A_2 | L_0) \leq P(A_2 | L')
\]  

According to the construction of \(L_0\) the \(u_i\) which happen to be zero have the smallest subscripts, the \(m_i\) which happen to be zero have the largest subscripts. More rigorously, there are subscripts \(r\) and \(s\) such that

\[
u_i = 0 \quad \text{if} \quad i \leq r - 1, \quad u_i > 0 \quad \text{if} \quad i \geq r
\]  

\[
m_i = 0 \quad \text{if} \quad i \geq s + 1, \quad m_i > 0 \quad \text{if} \quad i \leq s
\]  

We have seen previously that

\[
u_{\sigma(\mu)} > 0
\]
and
\[ m_{\alpha'(\lambda)} > 0 \]

hence
\[ n(\mu) \geq r \]
\[ n'(\lambda) \leq s \]

hence
\[ P_{i_1} = 1 \quad \text{for } i = 1, 2, \ldots, r - 1 \quad (23) \]
\[ P_{i_2} = 1 \quad \text{for } i = s + 1, s + 2, \ldots, N \quad (24) \]

that is, whenever \( u_i \) is zero then \( P_{i_1} = 1 \) and whenever \( m_i = 0 \) then \( P_{i_2} = 1 \).

By definition of \( \mu \), it follows that
\[ \sum_{i=1}^{N} u_i P_{i_1} = \sum_{i=1}^{N} u_i P'_{i_1} = \mu. \quad (25) \]

Putting \( n = n(\mu) \) and observing that \( P_{i_1} = 1 \) if \( i \leq n - 1 \) we can express (25) as follows:
\[ \sum_{i=1}^{n-1} u_i + u_n P_{i_1} = \sum_{i=1}^{N} u_i P'_{i_1} \]
or
\[ \sum_{i=1}^{n-1} u_i (1 - P'_{i_1}) + u_n (P_{i_1} - P'_{i_1}) = \sum_{i=n+1}^{N} u_i P'_{i_1}. \quad (26) \]

With the possible exception of the last term on the left it is clear that every term in (26) is non-negative. We assume, without loss of generality, that the term in question is non-negative for, if it were negative, we would simply transfer it to the other side of the equality and all of the steps to follow would hold. It follows that if not every term in (26) is equal to zero then both sides are positive. Assume for the moment that this is the case.

It follows from the ordering of \( \Gamma \) that
\[ u_i m_j \leq u_j m_i \quad \text{whenever } i < j. \quad (27) \]

It is now seen that
\[ \left[ \sum_{j=n+1}^{N} m_j P'_{j_1} \right] \left[ \sum_{i=1}^{n-1} u_i (1 - P'_{i_1}) + u_n (P_{i_1} - P'_{i_1}) \right] \]
\[ \leq \left[ \sum_{i=1}^{n-1} m_i (1 - P'_{i_1}) + m_n (P_{i_1} - P'_{i_1}) \right] \left[ \sum_{j=n+1}^{N} u_j P'_{j_1} \right] \quad (28) \]
since by (27) every term in the expansion of the left hand side is of the form
\[ m_j u_i P'_{j_1} (1 - P'_{i_1}) \quad \text{or} \quad m_j u_n P'_{j} (P_{i_1} - P'_{i_1}) \quad (i \leq n < j) \]
and corresponding to each there is a similar term on the right hand side but with \( m_iu_i \) replaced by \( m_iu_i \) and \( m_iu_i \) replaced by \( m_iu_i \). Dividing (28) by (26) we get

\[
\sum_{j=i+1}^{N_r} m_jP'_{ji} \leq \sum_{j=1}^{N_r} m_j(1 - P'_{ji}) + m_i(P_u - P'_{ii})
\]

or

\[
\sum_{i=1}^{N_r} m_iP'_{ii} \leq \sum_{i=1}^{N_r} m_iP_{ii}.
\]  \( \text{(29)} \)

If every term in (26) was zero (29) would still hold since in that case we would have

\[
P_{ii} = P'_{ii} \quad \text{for } i \geq r
\]

i.e. whenever \( u_i \neq 0 \) and we would have

\[
P_{ii} = 1 \geq P'_{ii} \quad \text{for } i \leq r - 1
\]

because of (23) and because \( P'_{ii} \leq 1 \) for every \( i \). Hence (29) would hold in this case as well.

By definition

\[
\sum_{i=1}^{N_r} m_iP'_{ii} = \sum_{i=1}^{N_r} m_iP_{ii} = \lambda.
\]  \( \text{(30)} \)

From (29) and (30) we get

\[
\sum_{i=1}^{N_r} m_i(P'_{ii} + P_{ii}) \leq \sum_{i=1}^{N_r} (P_{ii} + P_{ii})
\]

or

\[
\sum_{i=1}^{N_r} m_i(1 - P'_{ii}) \leq \sum_{i=1}^{N_r} m_i(1 - P_{ii}).
\]  \( \text{(31)} \)

Because

\[
\sum_{i=1}^{N_r} m_i = 1,
\]

we get

\[
\sum_{i=1}^{N_r} m_iP'_{ii} \leq \sum_{i=1}^{N_r} m_iP_{ii}
\]

or

\[
P_{ii}(A_i \mid M) \leq P_{ii}(A_i \mid M).
\]  \( \text{(32)} \)

It can be shown similarly that

\[
P_{ii}(A_i \mid U) \leq P_{ii}(A_i \mid U).
\]  \( \text{(33)} \)
But (32) and (33) together state that

$$P(A_2 \mid L_0) \leq P(A_2 \mid L')$$

(34)

which completes the proof of the first part of the theorem. Note that we have actually proved more than (34) since we have proved that $L_0$ is optimal separately under both the conditions $M$ and the condition $U$. This also explains why the prior probabilities $P(M)$ and $P(U)$ do not enter either the statement or the proof of the theorem; our result is independent of these prior probabilities. The underlying reason, of course, lies in the fact that the error levels are concerned with conditional probabilities of misallocation. The situation would change if one tried to minimize the unconditional probability of misallocation or if one tried to minimize some general loss function.

As for the proof of the second part, let $(\mu', \lambda')$ be an inadmissible pair of error levels $(0 < \mu < 1, 0 < \lambda < 1)$. Since $f(\mu)$ is a strictly monotone decreasing continuous function in the range determined by

\begin{align*}
0 &< \mu < 1 \\
0 &< f(\mu) < 1
\end{align*}

it will intersect at a unique point the straight line drawn through $(0, 0)$ and $(\mu', \lambda')$. This is illustrated in Figure 1. Denote this point by $(\mu_0, \lambda_0)$. Then

\begin{align*}
0 &< \mu_0 < \mu' < 1 \\
0 &< \lambda_0 < \lambda' < 1
\end{align*}

and

$$\lambda_0 = f(\mu_0).$$

(35)

The linkage rule $L_0(\mu_0, \lambda_0, \Gamma)$ is, in light of (36), (12), and (13) such that

$$P(A_2 \mid L_0) = 0.$$

Hence $L_0(\mu_0, \lambda_0, \Gamma)$ is a better linkage rule than any other linkage rule at the level $(\mu', \lambda')$.

This completes the full proof of our theorem.

The form of the theorem given in the text is an immediate corollary of the theorem above and the expression (11).

APPENDIX II

METHOD II FOR THE CALCULATION OF WEIGHTS

Denoting

$$N_A N_B = c$$

the equations resulting from (37) to (39) by dropping expected values can be written as

$$M_k = \frac{N}{c} \prod_{j=1,j \neq k}^1 m_j + \frac{c - N}{c} \prod_{j=1,j \neq k}^1 u_j \quad k = 1, 2, 3$$

(1)
We introduce the transformation

\[ m_k^* = m_k - U_k \quad \text{and} \quad u_k^* = u_k - U_k. \]  

Substituting \( m_k^* \) and \( u_k^* \) from (4) and (5) into (2) we obtain

\[ \frac{N}{c} m_k^* + \frac{c - N}{c} u_k^* = 0 \quad k = 1, 2, 3. \]  

Substituting (4) and (5) into (1) and then substituting in the resulting equations \( u_k^* \) from (6) we obtain

\[ \prod_{j=1,j \neq k}^{3} m_j^* = \frac{c - N}{N} \left[ M_k - \prod_{j=1,j \neq k}^{3} U_j \right] \quad k = 1, 2, 3. \]  

Denoting

\[ R_k = M_k - \prod_{j=1,j \neq k}^{3} U_j \quad k = 1, 2, 3 \]  

we obtain by multiplying the three equations under (7) and by taking square roots

\[ \prod_{j=1}^{3} m_j^* = \left( \frac{c - N}{N} \right)^{\frac{3}{2}} \left( \prod_{j=1}^{3} R_j \right)^{\frac{1}{2}} \]  

Dividing (9) by (7) and putting

\[ X = \sqrt{\frac{c - N}{N}} \]  

\[ B_k = \sqrt{\prod_{j=1,j \neq k}^{3} R_j/R_k} \quad k = 1, 2, 3 \]  

we get

\[ m_k^* = B_k X \quad k = 1, 2, 3 \]  

and, from (4) to (6),

\[ m_k = U_k + B_k X \quad k = 1, 2, 3 \]  

\[ u_k = U_k - B_k/X \quad k = 1, 2, 3. \]  

We can now substitute into (3) \( m_k \) and \( u_k \) from (13) and (14) respectively and \( N \) as expressed from (10). We obtain

\[ \frac{1}{X^2 + 1} \sum_{j=1}^{3} \left( U_j + B_j X \right) + \frac{X^2}{X^2 + 1} \left( U_j - B_j/X \right) = M. \]  

\[ 76 \]
After expanding (15), some cancellations and substitution of $B_k$ from (11) we get the following quadratic equation in $X$:

$$\sqrt{\prod_{j=1}^{3} R_j (X^2 - 1) + \left[ \prod_{j=1}^{3} U_j + \sum_{j=1}^{3} R_j U_j - M \right]} X = 0. \tag{16}$$

The positive root of this equation is

$$X = \left\{ M - \sum_{j=1}^{3} R_j U_j - \prod_{j=1}^{3} U_j \right\} \sqrt{\prod_{j=1}^{3} R_j} / \left(\prod_{j=1}^{3} R_j \right) \tag{17}$$

The estimates of $m_k$, $u_k$ and $N$ are now easily obtained from (10), (13) and (14).

Having solved these equations we can proceed to estimate the specific values of $m(\gamma)$ and $u(\gamma)$ which are required. We introduce some additional notation which, as before, refers to observable frequencies:

- $M_k(\gamma_i)$ = the proportion of “agreement” in all components except the $k$th; the specific configuration $\gamma_i^k$ in the $k$th component
- $U_1(\gamma_i) = $ the proportion of “agreement” in the first, $\gamma_i^1$ in the second and any configuration in the third component
- $U_2(\gamma_i) = $ the proportion of “agreement” in the first, $\gamma_i^2$ in the third and any configuration in the third component
- $U_3(\gamma_i) = $ the proportion of $\gamma_i^1$ in the first, “agreement” in the second and any configuration in the third component.

The required values of $m(\gamma_i^1)$ and $u(\gamma_i^1)$ are estimated as

$$m(\gamma_i^1) = \frac{M_1(\gamma_i) - u_2 U_2(\gamma_i)}{m_2(m_2 - u_2)} (X^2 + 1) \tag{18}$$

$$m(\gamma_i^2) = \frac{M_2(\gamma_i) - u_3 U_3(\gamma_i)}{m_1(m_2 - u_2)} (X^2 + 1) \tag{19}$$

$$m(\gamma_i^3) = \frac{M_3(\gamma_i) - u_3 U_3(\gamma_i)}{m_1(m_2 - u_2)} (X^2 + 1) \tag{20}$$

$$u(\gamma_i^1) = \frac{m_3 U_3(\gamma_i) - M_1(\gamma_i)}{u_3(m_2 - u_2)} \frac{X^2 + 1}{X^2} \tag{21}$$

$$u(\gamma_i^2) = \frac{m_3 U_3(\gamma_i) - M_2(\gamma_i)}{u_3(m_2 - u_2)} \frac{X^2 + 1}{X^2} \tag{22}$$

$$u(\gamma_i^3) = \frac{m_3 U_3(\gamma_i) - M_3(\gamma_i)}{u_3(m_2 - u_2)} \frac{X^2 + 1}{X^2} \tag{23}$$

The formulae (18) to (23) are easily verified by expressing the expected values of the quantities $M_k(\gamma_i)$, $U_k(\gamma_i)$, etc. in terms of $m_k$, $u_k$, $m(\gamma_i)$ and $u(\gamma_i)$.
dropping the expected values and solving the resulting equations (there will be two equations for each pair \( m(\gamma_k) \) and \( u(\gamma_k) \)).

The necessary and sufficient conditions for the mechanical validity of the formulae in this section are that

\[
m_k \neq u_k \quad k = 1, 2, 3
\]

and

\[
R_k > 0 \quad k = 1, 2, 3
\]

Since

\[
m_k = m(S_k) = \Pr(S_k | M)
\]
\[
u_k = u(S_k) = \Pr(S_k | T)
\]

clearly for sensible definitions of “agreement” \( m_k > u_k \) should hold for \( k = 1, 2, 3 \). In this case \( R_k > 0 \) will hold as well. The latter statement can easily be verified by substituting (1) and (2) into (8).
The necessity of linking records from two or more sources arises in many contexts. One good example would be merging files in order to extend the amount or improve the quality of information available for population units represented in both files. In developing procedures for linking records from two or more sources, tradeoffs exist between two types of mistakes: (1) the bringing together of records which are for different entities (mismatches), and (2) the failure to link records which are for the same entity (errorneous nonmatches). Whether or not one is able to utilize one's resources in an "optimal" way, it is almost certainly going to be true that in most situations of practical interest some mismatching and erroneous nonmatching will be unavoidable. How to deal with these problems depends, of course, to a great extent on the purposes for which the data linkage is being carried out. Because these reasons can be so diverse, no general strategy for handling mismatches and nonmatches will be offered here. Instead, we will examine the impact of these difficulties on the analysis of a specific study. The study chosen is a large-scale matching effort, now nearing completion, which had as its starting point the March 1973 Current Population Survey (CPS).

THE 1973 CENSUS - SOCIAL SECURITY
EXACT MATCH STUDY

The primary identifying information in the 1973 Census-Social Security study was the social security number (SSN). The problems which arise when using the SSN to link Current Population Survey interview schedules to Social Security records differ in degree, but not in kind, from the problems faced by other "matchmakers."

In the 1973 study, as in prior CPS-SSA linkages, the major difficulty encountered was incompleteness in the identifying information [1]. Manual searches had to be carried out at SSA for over 22,000 individuals for whom no SSN had been reported by the survey respondent [2]. Another major problem was reporting errors in the social security number or other identifiers (name and date of birth, etc.). SSN's were manually searched for at SSA in cases where severe discrepancies between the CPS and SSA information were found after matching the two sources using the account number initially provided [3]. Because of scheduling and other operational constraints, an upper limit of 4,000 manual searches had to be set for this part of the project. Therefore, it was possible to look for account numbers only in the most "likely" instances of CPS misreporting of the SSN. The cases sent through this search procedure were those for which both name and date of birth were in substantial disagreement. For social security beneficiaries, computerized (machine) searches at SSA were also conducted for both missing and misreported SSN's. This was made possible through an administrative cross-reference system which links together persons who receive benefits on the same claim number. About 1,000 potentially usable SSN's were obtained in this way.

Operational Restrictions on the Matching.-- One of the concerns the 1973 work has in common with earlier Census-SSA linkage efforts is the great care that is being taken to ensure the confidentiality of the shared information. The laws and regulations under which the agencies operate impose very definite restrictions on such exchanges, and special procedures have been followed throughout, so as to adhere to these provisions—in particular, to ensure that the shared information is used only for statistical purposes and not for administrative ones [1]. Another major restriction on the study was, of course, that it had to be conducted using data systems which were developed and are used principally for other purposes. The CPS, for instance, lacks a number of pieces of information that would, if available, have materially increased the chances of finding the surveyed individual in SSA's files. Finally, the manual searching for over 26,000 account numbers at Social Security imposed a sizable addition to the normal administrative workload in certain parts of the agency. Therefore, in order to obtain a reasonable priority for the project, numerous operational compromises were made which precluded the employment of "optimal" matching techniques [e.g., 4, 5, 6, 7, 8]. One of the most serious of these was the decision basically not to "re-search" for the missing and misreported SSN's of individuals for whom no potentially usable number was found after just one search.

Basic Match Results.--There were 101,287 interviewed persons age 14 or older who were included in the 1973 Census-Social Security Exact Match Study. Of the total, about 2 percent had not yet been issued an SSN at the time of the interview and, hence, were not eligible for matching. In another 8 percent of the cases, no potentially usable social security numbers could be found even though one was believed to exist. For the remaining 90,815 sampled individuals, an SSN was available, and CPS and SSA data could be linked. Of these account numbers, 77,465 were supplied by CPS respondents initially. There were also 3,347 cases where the SSN provided originally was replaced with an account number obtained from the manual and machine searches of SSA's files which were described above. In a few of these cases—about 200—the SSN's used as replacements were taken from a supplementary Census source. Finally, there were 10,003 sampled individuals for whom no account number had been provided initially, but one was obtained subsequently by a search of SSA's files.

ALTERNATIVE COMPUTERIZED MATCH RULES

In general, aside from certain obvious errors (which have already been eliminated), it is not
