Lecture 14 - inheritance

Steve Gribble

Department of Computer Science & Engineering
University of Washington

Today

C++ inheritance

- *huge thanks to Marty Stepp for his “portfolio” case study*

Let's build a stock portfolio

A portfolio represents a person's financial investments

- each asset has a cost (how much was paid for it) and a market value (how much it is worth)
 - the difference is the profit (or loss)
- different assets compute market value in different ways
 - **stock**: has a symbol ("GOOG"), a number of shares, share price paid, and current share price
 - **dividend stock**: is a stock that also has dividend payments
 - **cash**: money; never incurs profit or loss. (hah!)

One possible design

One class per asset type

- Problem: redundancy
- Problem: cannot treat multiple investments the same way
 - ▶ e.g., cannot put them in a single array or Vector

see initial_design/

Inheritance

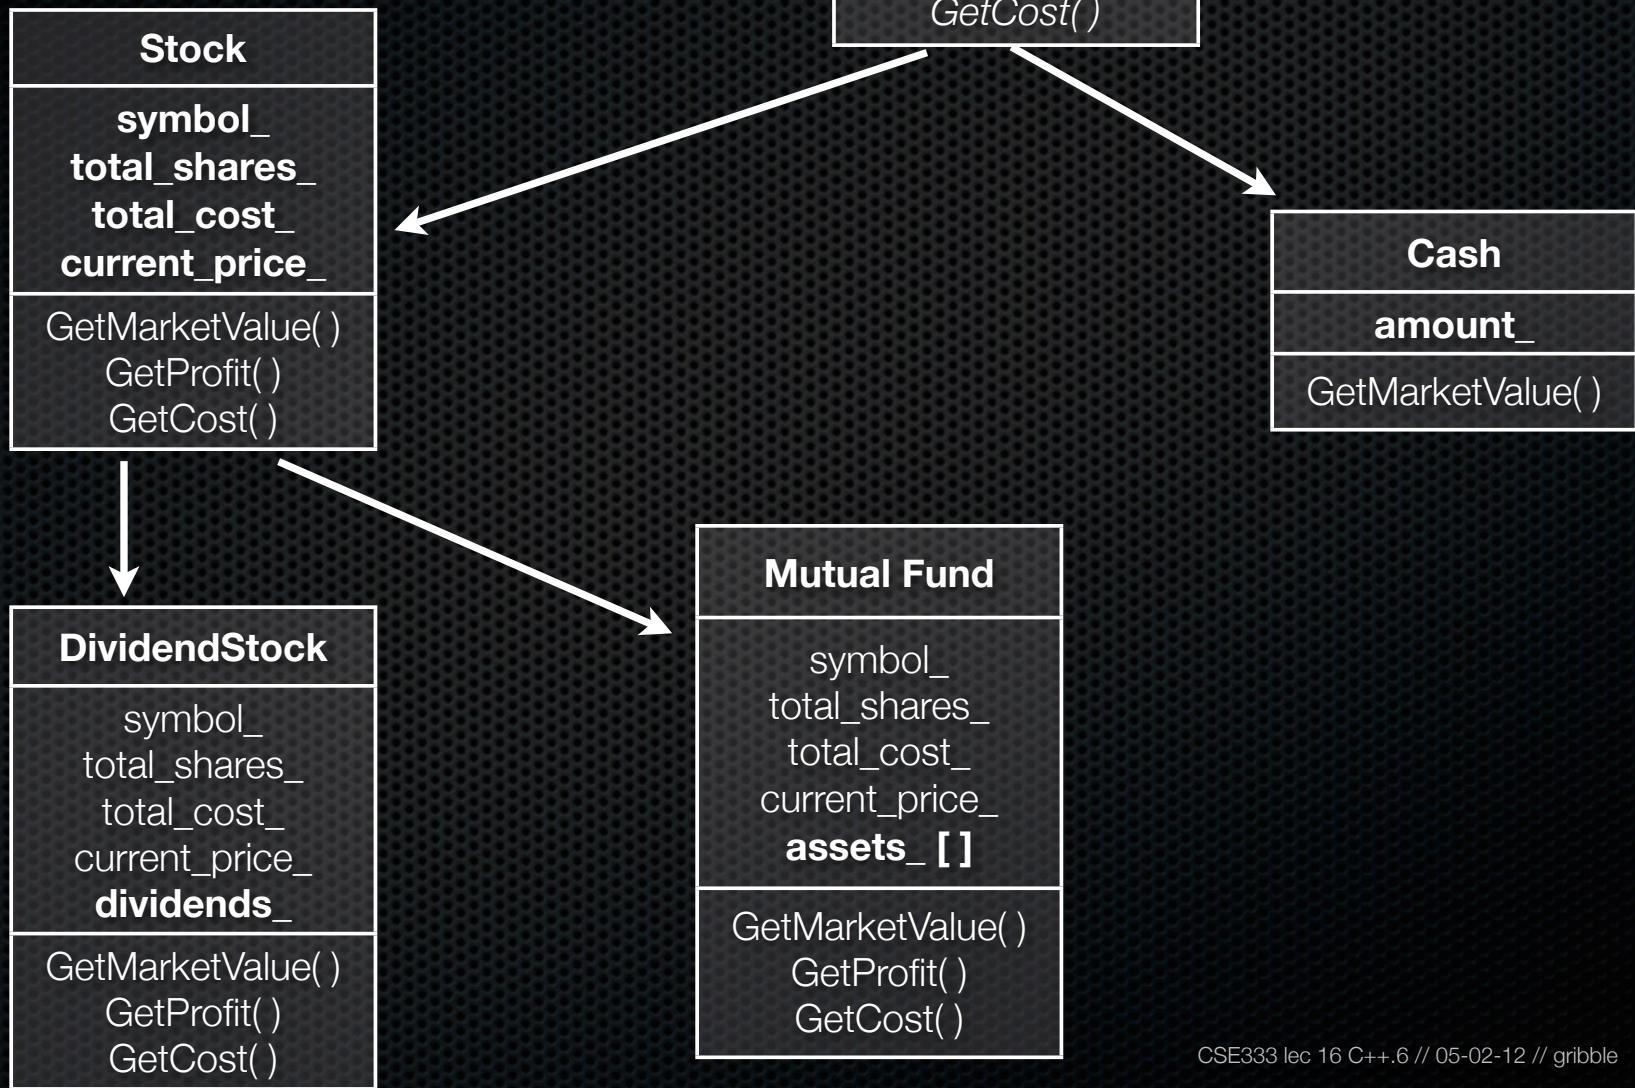

A parent-child relationship between classes

- a child (**derived** class) extends a parent (**base** class)

Benefits:

- code reuse: subclasses inherit code from superclasses
- polymorphism
 - ability to redefine existing behavior but preserve the interface
 - children can override behavior of parent
 - others can make calls on objects without knowing which part of the inheritance tree it is in
- extensibility: children can add behavior

Better design

Access specifiers

public: visible to all other classes

protected: visible to current class and its subclasses

private: visible only to the current class

declare a member as **protected** if:

- you don't want random customers accessing them
 - ▶ you want to be subclassed and to let subclasses access them

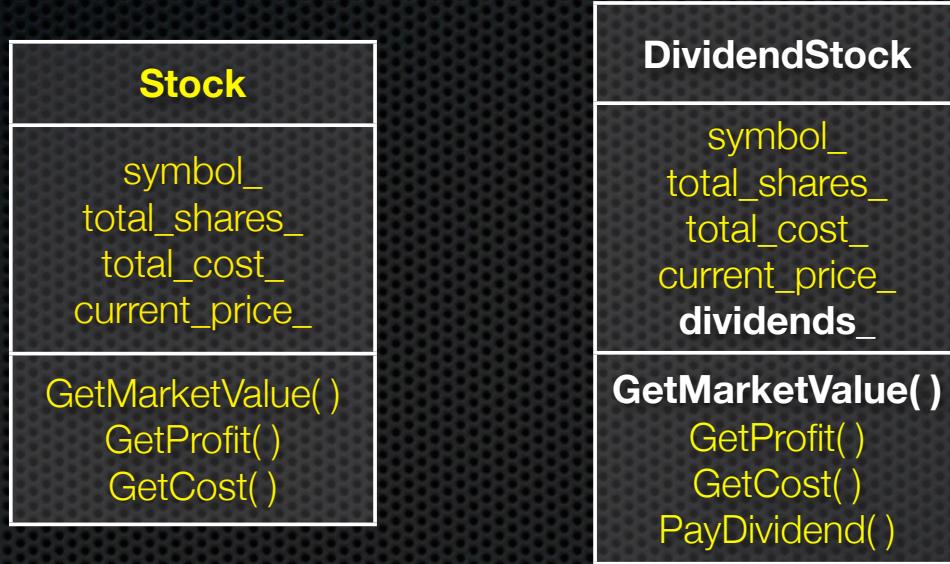

Public inheritance

```
#include "BaseClass.h"

class Name : public BaseClass {
    ...
};
```

- “public” inheritance
 - ▶ anything that is [*public, protected*] in the base is [*public, protected*] in the derived class
- derived class inherits **almost** all behavior from the base class
 - ▶ not constructors and destructors
 - ▶ not the assignment operator or copy constructor

Revisiting the portfolio example

Without inheritance (separate class per type)

- lots of redundancy
- no type relationship between the classes

Revisiting the portfolio example

A derived class:

- **inherits** the behavior and state of the base class
- **overrides** some of the base class's member functions
- **extends** the base class with new member functions, variables

(implement better_design/)

Static dispatch

When a member function is invoked on an object

- the code that is invoked is decided at compile time, based on the compile-time visible type of the callee

```
double DividendStock::GetMarketValue() const {
    return get_shares() * get_share_price() + _dividends;
}

double DividendStock::GetProfit() const {
    return GetMarketValue() - GetCost();
}
```

DividendStock.cc

```
double Stock::GetMarketValue() const {
    return get_shares() * get_share_price();
}

double Stock::GetProfit() const {
    return GetMarketValue() - GetCost();
}
```

Stock.cc

CSE333 lec 16 C++.6 // 06-02-12 // gribble

Static dispatch

```
DividendStock dividend();

DividendStock *ds = &dividend;
Stock *s = &dividend;

// invokes Stock::GetProfit(), since that function is
// inherited (i.e, not overridden). Stock::GetProfit()
// invokes Stock::GetMarketValue(), since C++ uses
// static dispatch by default.
ds->GetProfit();

// invokes DividendStock::GetMarketValue()
ds->GetMarketValue();

// invokes Stock::GetMarketValue()
s->GetMarketValue();
```

(see *even_better_design/*)

Dynamic dispatch

When a member function is invoked on an object

- the code that is invoked is decided at run time, and is the **most-derived function** accessible to the object's visible type

```
double DividendStock::GetMarketValue() const {
    return get_shares() * get_share_price() + _dividends;
}
```

```
double DividendStock::GetProfit() const {
    return DividendStock::GetMarketValue() - GetCost();
}
```

DividendStock.cc

```
double Stock::GetMarketValue() const {
    return get_shares() * get_share_price();
}
```

```
double Stock::GetProfit() const {
    return GetMarketValue() - GetCost();
}
```

Stock.cc

CSE333 lec 16 C++.6 // 06-02-12 // gribble

Dynamic dispatch

```
DividendStock dividend();

DividendStock *ds = &dividend;
Stock *s = &dividend;

// invokes Stock::GetProfit(), since that function is
// inherited (i.e, not overridden). Stock::GetProfit()
// invokes Dividend::GetMarketValue(), since that is
// the most-derived accessible function.
ds->GetProfit();

// invokes DividendStock::GetMarketValue()
ds->GetMarketValue();

// invokes DividendStock::GetMarketValue()
s->GetMarketValue();
```

Dynamic dispatch

Here's what "most derived" means:

```
class A {  
public:  
    // Foo will use dynamic dispatch  
    virtual void Foo();  
};  
  
class B : public A {  
public:  
    // B::Foo overrides A::Foo  
    virtual void Foo();  
};  
  
class C : public B {  
public:  
    // C inherits B::Foo()  
};
```

```
void function() {  
    A *a_ptr;  
    C c;  
  
    // Why is this OK?  
    a_ptr = &c;  
  
    // Whose Foo() is called?  
    a_ptr->Foo();  
}
```

But how can this possibly work??

The compiler produces Stock.o from Stock.cc

- while doing this, it can't know that DividendStock exists
 - so, how does the code emitted for Stock::GetProfit() know to invoke Stock::GetMarketValue() some of the time, and DividendStock::GetMarketValue() other times???!?

```
virtual double Stock::GetMarketValue() const;  
virtual double Stock::GetProfit() const; Stock.h
```

```
double Stock::GetMarketValue() const {  
    return get_shares() * get_share_price();  
}  
  
double Stock::GetProfit() const {  
    return GetMarketValue() - GetCost();  
}
```

Stock.cc

CSE333 lec 16 C++ 6 // 05-02-12 // gribble

vtables and the vptr

If a member function is virtual, the compiler emits:

- a “vtable”, or virtual function table, **for each class**
 - ▶ it contains an function pointer for each virtual function in the class
 - ▶ the pointer points to the most-derived function for that class
- a “vptr”, or virtual table pointer, **for each object instance**
 - ▶ the vptr is a pointer to a virtual table, and it is essentially a hidden member variable inserted by the compiler
 - ▶ when the object’s constructor is invoked, the vptr is initialized to point to the virtual table for the object’s class
 - ▶ thus, the vptr “remembers” what class the object is

vtable/vptr example

```
class Base {  
public:  
    virtual void fn1() {};  
    virtual void fn2() {};  
};  
  
class Dr1: public Base {  
public:  
    virtual void fn1() {};  
};  
  
class Dr2: public Base {  
public:  
    virtual void fn2() {};  
};
```

```
// what needs to work  
  
Base b;  
Dr1 d1;  
Dr2 d2;  
  
Base *bptr = &b;  
Base *d1ptr = &d1;  
Base *d2ptr = &d2;  
  
bptr->fn1(); // Base::fn1()  
bptr->fn2(); // Base::fn2()  
  
d1ptr->fn1(); // Dr1::fn1()  
d1ptr->fn2(); // Base::fn2()  
  
d2.fn1(); // Base::fn1()  
d2ptr->fn1(); // Base::fn1()  
d2ptr->fn2(); // Dr2::fn2()
```

vtable/vptr example

```
// what happens

Base b;
Dr1 d1;
Dr2 d2;

Base *d2ptr = &d2;

d2.fn1();
// d2.vptr -->
// Dr2.vtable.fn1 -->
// Base::fn1()

d2ptr->fn2();
// d2ptr -->
// d2.vptr -->
// Dr2.vtable.fn1 ->
// Base::fn1()
```

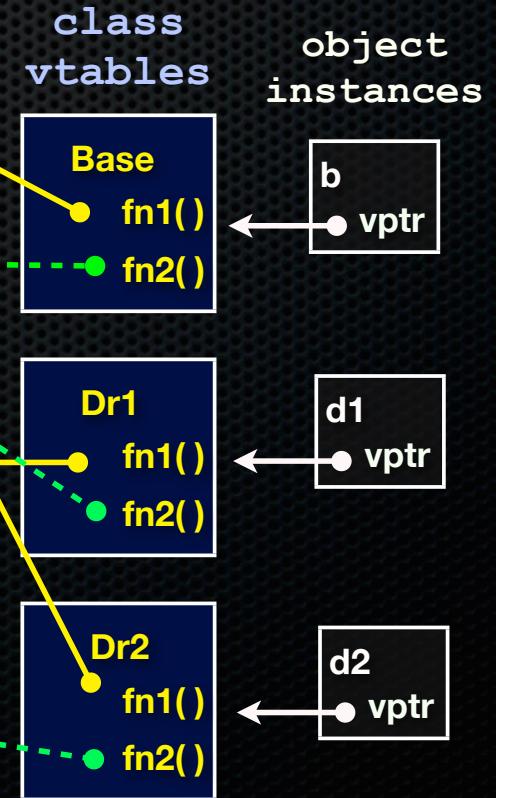

compiled code

```
Base :: fn1()
    mov (%eax),%eax
    add $0x18,%eax
    ...

Base :: fn2()
    add $0x1c,%eax
    sub $0x4,%esp
    ...

Dr1 :: fn1()
    add $0x1c,%eax
    mov (%eax),%eax
    ...

Dr2 :: fn2()
    sub $0x4,%esp
    mov (%eax),%eax
    ...
```

actual code

```
class Base {
public:
    virtual void fn1() {};
    virtual void fn2() {};
};

class Dr1: public Base {
public:
    virtual void fn1() {};
};

main() {
    Dr1    d1;
    d1.fn1();
    Base *ptr = &d1;
    ptr->fn1();
}
```

vtable.cc

Let's compile this and use objdump to see what g++ emits!

- g++ -g vtable.cc
- objdump -CDSRTtx a.out | less

Inheritance and constructors

A derived class **does not inherit** the base class's constructor

- the derived class ***must*** have its own constructor
 - if you don't provide one, C++ synthesizes a default constructor for you
 - it initializes derived class's member variables to zero-equivalents and invokes the default constructor of the base class
 - if the base class has no default constructor, a compiler error
- a constructor of the base class is invoked before the constructor of the derived class
 - you can specify which base class constructor in the initialization list of the derived class, or C++ will invoke default constructor of base class

Examples

```
// Base has no default constructor
class Base {
public:
    Base(int x) : y(x) { }
    int y;
};

// Compiler error when you try
// to instantiate a D1, as D1's
// synthesized default constructor
// needs to invoke Base's default
// constructor.
class D1 : public Base {
public:
    int z;
};

// Works.
class D2 : public Base {
public:
    D2(int z) : Base(z+1) {
        this->z = z;
    }
    int z;
};
```

badcons.cc

```
// Base has a default constructor.
class Base {
public:
    int y;
};

// Works.
class D1 : public Base {
public:
    int z;
};

// Works.
class D2 : public Base {
public:
    D2(int z) {
        this->z = z;
    }
    int z;
};
```

goodcons.cc

Destructors

When the destructor of a derived class is invoked...

- the destructor of the base class is invoked after the destructor of the derived class finishes

Note that static dispatch of destructors is almost always a mistake!

- good habit to always define a destructor as virtual
 - ▶ empty if you have no work to do

baddestruct.cc

```
class Base {
public:
    Base() { x = new int; }
    ~Base() { delete x; }
    int *x;
};

class D1 : public Base {
public:
    D1() { y = new int; }
    ~D1() { delete y; }
    int *y;
};

Base *b = new Base;
Base *dptr = (Base *) new D1;

delete b;      // ok
delete dptr; // leaks D1::y
```

Slicing -- C++'s revenge

C++ allows you to...

- assign to...
 - ▶ an instance of a base class...
 - ▶ the value of a derived class

slicing.cc

```
class Base {  
public:  
    Base(int x) : x_(x) {}  
    int x_;  
};  
  
class Dr : public Base {  
public:  
    Dr(int y) : Base(16), y_(y) {}  
    int y_;  
};  
  
main() {  
    Base b(1);  
    Dr d(2);  
    b = d; // what happens to y_?  
    // d = b; // compiler error  
}
```

Given this, STL containers?? :(

STL stores **copies of values** in containers, not pointers to object instances

- so, what if you have a class hierarchy, and want to store mixes of object types in a single container?
 - e.g., Stock and DividendStock in the same list
- you get sliced! :(

```
class Stock {  
    ...  
};  
  
class DivStock : public Stock {  
    ...  
};  
  
main() {  
    Stock      s;  
    DivStock   ds;  
    list<Stock> li;  
  
    li.push_back(s); // OK  
    li.push_back(ds); // OUCH!  
}
```

STL + inheritance: use pointers?

Store pointers to heap-allocated objects in STL containers

- no slicing :)
 - ▶ you have to remember to delete your objects before destroying the container :(
 - ▶ sort() does the wrong thing :(:(

Use smart pointers!

```
#include <list>
using namespace std;

class Integer {
public:
    Integer(int x) : x_(x) { }
private:
    int x_;
};

main() {
    list<Integer *> li;
    Integer *i1 = new Integer(2);
    Integer *i2 = new Integer(3);

    li.push_back(i1);
    li.push_back(i2);
    li.sort(); // waaaaah!!
}
```

Explicit casting in C

C's *explicit typecasting* syntax is simple

```
lhs = (new type) rhs;
```

- C's explicit casting is used to...
 - ▶ convert between pointers of arbitrary type
 - ▶ forcibly convert a primitive type to another
 - e.g., an integer to a float, so that you can do integer division

```
int x = 5;
int y = 2;
printf("%d\n", x / y);           // prints 2
printf("%f\n", ((float) x) / y); // prints 2.5
```

C++

You can use C-style casting in C++, but C++ provides an alternative style that is more informative

- `static_cast<to_type>(expression)`
- `dynamic_cast<to_type>(expression)`
- `const_cast<to_type>(expression)`
- `reinterpret_cast<to_type>(expression)`

static_cast

C++'s static_cast can convert:

- pointers to classes **of related type**
 - get a compiler error if you attempt to static_cast between pointers to non-related classes
 - dangerous to cast a pointer to a base class into a pointer to a derived class
- non-pointer conversion
 - float to int, etc.

static_cast is checked at compile time

staticcast.cc

```
class Foo {  
public:  
    int x_;  
};  
  
class Bar {  
public:  
    float x_;  
};  
  
class Wow : public Bar {  
public:  
    char x_;  
};  
  
int main(int argc, char **argv) {  
    Foo a, *aptr;  
    Bar b, *bptr;  
    Wow c, *cptr;  
  
    // compiler error  
    aptr = static_cast<Foo *>(&b);  
  
    // OK  
    bptr = static_cast<Bar *>(&c);  
  
    // compiles, but dangerous  
    cptr = static_cast<Wow *>(&b);  
    return 0;  
}
```

CSE333 lec 19 C++,8 network // 05-13-11 // gribble

dynamic_cast

C++'s dynamic_cast can convert:

- pointers to classes of related type
- references to classes of related type

dynamic_cast is checked at both compile time and run time

- casts between unrelated classes fail at compile time
- casts from base to derived fail at run-time if the pointed-to object is not a full derived object

dynamiccast.cc

```
class Base {  
public:  
    virtual int foo() { return 1; }  
    float x_;  
};  
  
class Deriv : public Base {  
public:  
    char x_;  
};  
  
int main(int argc, char **argv) {  
    Base b, *bptr = &b;  
    Deriv d, *dptr = &d;  
  
    // OK (run-time check passes).  
    bptr = dynamic_cast<Base *>(&d);  
    assert(bptr != NULL);  
  
    // OK (run-time check passes).  
    dptr = dynamic_cast<Deriv *>(bptr);  
    assert(dptr != NULL);  
  
    // Run-time check fails, so the  
    // cast returns NULL.  
    bptr = &b;  
    dptr = dynamic_cast<Deriv *>(bptr);  
    assert(dptr != NULL);  
  
    return 0;  
}
```

const_cast

Is used to strip or add const-ness

- dangerous!

```
void foo(int *x) {                                constcast.cc
    *x++;
}

void bar(const int *x) {
    foo(x); // compiler error
    foo(const_cast<int *>(x)); // succeeds
}

main() {
    int x = 7;
    bar(&x);
}
```

reinterpret_cast

casts between incompatible types

- storing a pointer in an int, or vice-versa
 - ▶ works as long as the integral type is “wide” enough
- converting between incompatible pointers
 - ▶ dangerous!

Implicit conversion

The compiler tries to infer some kinds of conversions

- when you don't specify an explicit cast, and types are not equal, the compiler looks for an acceptable implicit conversion

```
void bar(std::string x);

void foo() {
    int x = 5.7;      // implicit conversion float -> int
    bar("hi");        // implicit conversion, (const char *) -> string
    char c = x;        // implicit conversion, int -> char
}
```

Sneaky implicit conversions

How did the (const char *) --> string conversion work??

- if a class has a constructor with a single parameter, the compiler will exploit it to perform implicit conversions
- at most one user-defined implicit conversion will happen
 - ▶ can do int --> Foo
 - ▶ can't do int --> Foo --> Baz

```
class Foo {
public:
    Foo(int x) : x_(x) { }
    int x_;
};

int Bar(Foo f) {
    return f.x_;
}

int main(int argc, char **argv) {
    // The compiler uses Foo's
    // (int x) constructor to make
    // an implicit conversion from
    // the int 5 to a Foo.

    // equiv to return Bar(Foo(5));
    // !!!
    return Bar(5);
}
```

implicit.cc

Avoiding sneaky implicits

Declare one-argument constructors as “explicit” if you want to disable them from being used as an implicit conversion path

- usually a good idea

explicit.cc

```
class Foo {
public:
    explicit Foo(int x) : x_(x) { }
    int x_;
};

int Bar(Foo f) {
    return f.x_;
}

int main(int argc, char **argv) {
    // compiler error
    return Bar(5);
}
```

Exercise 1

Design a class hierarchy to represent shapes:

- examples of shapes: Circle, Triangle, Square

Implement methods that:

- construct shapes
- move a shape (i.e., add (x, y) to the shape position)
- returns the centroid of the shape
- returns the area of the shape
- Print(), which prints out the details of a shape

Exercise 2

Implement a program that:

- uses your exercise 1
 - ▶ constructs a vector of shapes
 - ▶ sorts the vector according to the area of the shape
 - ▶ prints out each member of the vector
- notes:
 - ▶ to avoid slicing, you'll have to store pointers in the vector
 - ▶ to be able to sort, you'll have to implement a wrapper for the pointers, and you'll have to override the “<” operator

See you on Friday!
