Question 1. (18 points) The traditional C++ hacking question. Complete the function HasDups on the next page so it returns true (1) if its argument contains more than one copy of some string, and returns false (0) if all of the strings are different. For example, if the input list contains {"apple", "banana", "cherry", "banana", "kumquat" } the HasDups function should return true ("banana" appears more than once). If the input is {"apple", "banana", "cherry", "kumquat" } the function should return false.

For full credit, your function must scan the input list only once. You will need to use some other container to keep track of the words found in the list, but this must be a set, map, or some other container that provides operations that can check for duplicates in time faster than O(n) (i.e., you cannot store the words in a new list and scan or sort the entire list looking for duplicates).

Hints and (incomplete) reference information:

- Remember that a STL list is a linked list underneath, so you must use iterators to scan it; you can't use [] subscripts to access individual list elements.
- If lst is a STL list, then lst.begin() and lst.end() return iterator values of type list<...>::iterator that might be useful.
- If it is an iterator, then *it can be used to reference the item it currently points to, and ++it will advance it to the next item, if any.
- Some useful operations on STL containers, including list:
 - o c.clear() remove all elements from c
 - o c.size() return number of elements in c
 - o c.empty() true if number of elements in c is 0, otherwise false
 - o c.push back (x) copy x to end of c
 - o c.push front (x) copy x to front of c
- Some additional operations on STL containers including set and map:
 - o c.insert(x) add copy of x to c (a key-value pair for a map, a value for a set)
 - o c.count(x) number of items in c with key x (returns only 0 or 1 for a set)
- You are free to use the C++11 auto keyword, C++11-style for-loops for iterating through containers, and any other features of standard C++11, but you are not required to use these.

(Write your answer on the next page. You may remove this page from the exam if you wish.)

Question 1. (cont.) Complete the definition of function HasDups below. Some useful #include directives as well as a using directive have been provided for convenience. You should add any additional libraries or code that you need.

```
#include <string>
#include <list>
#include <set>
using namespace std;
// Return true if the list words contains two or more
// copies of some string, otherwise return false.
bool HasDups(const list<string> &words) {
  set<string> wordset;
  for (auto w : words) {
    if (wordset.count(w) != 0) {
      return true;
    }
    wordset.insert(w);
  }
  return false;
}
```

Solutions using explicit iterators (wordset.begin(), wordset.end()) or using a map to check for duplicates were also fine.

Question 2. (19 points) The following header file defines a class that holds a pair of integers and includes a constructor and functions for accessing the values.

```
#ifndef _Pair_h_
#define Pair h
template <class T>
class Pair {
public:
  // Construct a Pair with given first and second values
  Pair(int T first, int T second)
      : first (first), second (second) { }
  // accessors: return first and second items from Pair
  int T first() const { return first; }
  int T second() const { return second ; }
private:
  // instance variables
  int T first;
  int T second ;
};
#endif // _Pair_h_
```

(a) (6 points) We would like to generalize this class so it can be used to store any pairs of values as long as the values have the same type (i.e., pairs of ints or pairs of strings, etc.)

Show the changes needed to make this a generic class where the element type is a type parameter instead of int. You should write your changes and additions in the above code. Hint: you'll need to start by adding template <class T> (or template <typename T>, which is equivalent) at the beginning of the class definition.

(Changes shown in green bold above)

(continued on the next page)

Question 2. (cont.) We would now like to add an addition (+) operator to the generic Pair class on the previous page. If (a,b) and (c,d) are Pair values, then (a,b)+(c,d) should yield a new Pair containing (a+c, b+d). Neither of the original Pair objects should be modified. You do not need to check that addition (+) is defined on the items stored in a Pair – that is handled for you by the compiler when the addition operator is used.

(b) (5 points) Write the function declaration (not the implementation) to be added to the header file Pair.h for the new operator+.

```
// return a new Pair that is the element-wise sum of
// this and other
Pair<T> operator+(const Pair<T> &other) const;
```

(You did not need to supply a comment, although that would be expected in a real project.)

(c) (8 points) Give the code to implement this new addition operator as it would appear in a separate file Pair.cc containing definitions of functions not implemented in Pair.h. Hint: the implementation needs to begin with template <class T>.

(The file containing this template would have to #include the Pair.h header, and client code would need to include both the header and implementation to use it. That wouldn't make any difference in how the template is written and was not considered while grading.)

Question 3. (18 points) Is it real or virtual? Consider the following program. Function names are in **bold** text to make them easier to find. (You may remove this page to use while answering the questions on the next page.)

```
#include <iostream>
#include <string>
using namespace std;
class Book {
 public:
  Book(string title) { title = new string(title); }
  virtual ~Book() { delete title ; }
  virtual string get title() const { return *title ; }
          string get description() const {
                   return "book: " + get title(); }
  virtual string get info() const {
                   return get_description() + " on main floor"; }
private:
  string *title ; // book title (on heap)
};
class Textbook : public Book {
 public:
  Textbook(string title, string subject) : Book(title) {
                               subject = new string(subject); }
  virtual ~Textbook() { delete subject ; }
          string get description() const {
           return "textbook for "+ *subject +": "+ get_title();}
  virtual string get info() const {
           return get description() + " in the basement"; }
 private:
  string *subject ; // book subject area (on heap)
};
int main() {
  Book *b = new Book("C++ Reference");
  Book *t = new Textbook("C++ Primer", "CSE");
  cout << b->get description() << endl;</pre>
  cout << b->get info() << endl;</pre>
  cout << t->get description() << endl;</pre>
  cout << t->get info() << endl;</pre>
  delete b:
  delete t;
  return 0;
}
```

Question 3. (cont.) (a) (6 points) What output does this program produce when it is executed? (And it does execute and produce output.) Hint: be sure you look at what the code actually does, not what you think it should do. \odot

book: C++ Reference

book: C++ Reference on main floor

book: C++ Primer

textbook for CSE: C++ Primer in the basement

(b) (3 points) Are there any C++ errors when this program executes? Examples might include memory management bugs, object slicing on assignment, incorrect casts to the wrong type, etc. Give a brief, concise description of the problems or indicate that there are none.

None

(c) (6 points) Now suppose we edit this program and remove *all* occurrences of the word virtual from the code. When we recompile and execute it, what output does it produce? If it is the same as before you can just say so; if it is different, either write all of the output, or indicate *clearly* exactly how it is different.

The last line is different:

book: C++ Reference

book: C++ Reference on main floor

book: C++ Primer

book: C++ Primer on main floor

(d) (3 points) When we execute this modified program with all of the virtuals removed, are there any hidden C++ errors this time? Again, give a very brief description.

Yes. Since the destructors are not virtual, when t is deleted, the ~Textbook destructor does not get executed and subject_ is not deleted. That results in a memory leak.

Question 4. (12 points) A walk down memory lane. We have a small mystery program that prints out the addresses contained in four of its pointer variables. We tried running this program several times and each time it produced somewhat different output!

```
\begin{array}{l} p=0x1e21010,\,q=0x000000,\,r=0x7fff47d7f83c,\,s=0x601060\\ p=0x9b9010,\,q=0x0000000,\,r=0x7fffe417e5fc,\,s=0x601060\\ p=0x11bc010,\,q=0x0000000,\,r=0x7fff59b03dcc,\,s=0x601060\\ p=0x10c0010,\,q=0x0000000,\,r=0x7fff6f61a75c,\,s=0x601060\\ p=0xd47010,\,q=0x0000000,\,r=0x7fffca4adb3c,\,s=0x601060\\ \end{array}
```

(a) (4 points) What's going on here? Why do we get different results when we run the same program repeatedly? It is exactly the same executable binary program run on the same system with no code changes, recompiling or relinking. So why the differences? (be brief, please)

Address space randomization. Each time the program is executed the stack and heap have somewhat different starting addresses.

(b) (8 points) We don't know for sure what the program does, but we do know that all of the pointers whose values are printed have type int*, and all of them have been initialized to point to a different region in the process address space if they point to anything at all. For each pointer, circle the answer that best describes the part of the process address space that the pointer value (address) references. Circle "can't tell" if there really isn't enough information to make a decision or at least a highly educated guess.

p:	stack	heap	global/static	NULL	can't tell
q:	stack	heap	global/static	NULL	can't tell
r:	stack	heap	global/static	NULL	can't tell
s:	stack	heap	global/static	NULL	can't tell

Question 5. (10 points) Oh, what tangled threads we weave. Consider the following small program, which compiles and executes without any errors. (#includes omitted to save space.)

```
int x = 0;
void * worker(void * ignore) {
  int y = 0;
  y = y + 1;
  x = x + y;
  printf("x = %d, y = %d\n", x, y);
  return NULL;
int main() {
  pthread t t1, t2; int ignore;
  ignore = pthread create(&t1, NULL, &worker, NULL);
  ignore = pthread create(&t2, NULL, &worker, NULL);
  x = x + 1;
  pthread join(t1, NULL);
  pthread join(t2, NULL);
  printf("final x = %d n", x);
  return 0;
}
```

(a) (7 points) What output is produced by this program when it executes? If it is possible to get different output when the program is executed a second time, write two different possible outputs from two different executions. If the program always produces the same output, give that output and indicate that it is always the same.

Here are a few possible outputs:

```
x = 2, y = 1 x = 3, y = 1 x = 1, y = 1

x = 3, y = 1 x = 2, y = 1 x = 2, y = 1

final x = 3 final x = 2
```

The threads all share the single global variable x, and the threads can run in any order once they are created. Further, fetching an old value of x and storing a new one can be interrupted by a context switch to another thread in between, and a thread can fetch x but then not print its value until after other threads have executed further. Each worker thread has its own private copy of y.

(b) (3 points) Circle *all* of the possible values that variable x could have at the end of different executions, as printed in the final line of output:

```
0 1 2 3 4 5 6 or greater
```

Question 6. (10 points) A fork in the road. Now consider the following program that is basically the same as the previous one, except that it uses fork instead of pthreads for concurrency. (#includes omitted again to save space.)

```
int x = 0;
void worker() {
  int y = 0;
  y = y + 1;
  x = x + y;
  printf("x = %d, y = %d\n", x, y);
int main() {
 pid t p1, p2; int ignore;
 p1 = fork();
  if (p1 == 0) {
   worker();
  } else {
    p2 = fork();
    if (p2 == 0) {
      worker();
    } else {
      x = x + 1;
      waitpid(p1, &ignore, 0);
      waitpid(p2, &ignore, 0);
      printf("final x = %d n", x);
    }
  return 0;
}
```

(a) (7 points) What output is produced by this program when it executes? If it is possible to get different output when the program is executed a second time, write two different possible outputs from two different executions. If the program always produces the same output, give that output and indicate that it is always the same.

The output will always appear to be:

```
x = 1, y = 1

x = 1, y = 1

final x = 1
```

However, the subprocesses that print the first two lines could print them in either order. In grading we allowed "always the same" since there is no visible difference.

(b) (3 points) Circle *all* of the possible values that variable \times could have at the end of different executions, as printed in the final line of output:

0 (1) 2 3 4 5 6 or greater

Question 7. (12 points) Sockets and packets, oh my! Circle true or false for each of the following statements.

true

false

TCP guarantees reliable delivery of the packets that make up a stream, assuming that the socket doesn't fail because of an I/O error.

true

false

IP guarantees reliable delivery of packets, assuming that the socket doesn't fail because of an I/O error.

Packets are delivered on a "best effort" basis, but may be dropped along the way due to congestion, routing problems, or other issues.

true

false

Given a particular hostname (like www.amazon.com), getaddrinfo() will return a single IP address corresponding to that name.

getaddrinfo() returns a list of possible addresses.

true

false

A single server machine can handle connection requests sent to multiple IP addresses.

true

false

The listen function returns a file descriptor number for a socket that a server can use to exchange data with the connected client machine.

listen instructs the operating system to queue up incoming connection requests from clients on a particular socket file descriptor. accept returns a file descriptor the server can use to exchange messages with clients.

true

false

A router stores information about the complete path needed to send a IP packet to its destination.

Routers generally know which of their neighbors would be a good bet to forward a packet on the next hop towards its destination, but they generally do not have detailed information beyond that.

Question 8. (1 free point) What are you planning to do during Spring Vacation? (Circle all that apply)
a) Sleep
b) Do laundry
c) Clear out biology experiments that have grown in the refrigerator
d) Write code for projects that didn't get done because of classes this quarter
e) Party
f) Travel to a warm location and sit on the beach
g) Travel to a cold location and go skiing, snowboarding, or something similar
h) Catch up on missed episodes of
i) Read a book not related to computing, technology, or work
j) Put in extra hours at work
k) Spring break??? You're kidding!!!! I'm already behind in my spring classes!!
l) Other
m) I'm not telling you, but please give me my free point
n) I don't know yet, but please give me my free point

Whatever you're planning to do, have a great break!

The CSE 333 staff

All answers received the point.
