

CSE 351 Section 4 – x86-64 Assembly

Hi there! Welcome back to section, we're happy that you're here ☺

x86-64 Assembly Language

Assembly language is a human-readable representation of machine code instructions (generally a one-to-one correspondence). Assembly is machine-specific because the computer architecture and hardware are designed to execute a particular machine code instruction set.

x86-64 is the primary 64-bit instruction set architecture (ISA) used by modern personal computers. It was developed by Intel and AMD and its 32-bit predecessor is called IA32. x86-64 is designed for complex instruction set computing (CISC), generally meaning it contains a larger set of more versatile and more complex instructions.

For this course, we will utilize only a small subset of x86-64's instruction set and omit floating point instructions.

x86-64 Instructions

The subset of x86-64 instructions that we will use in this course take either one or two operands, usually in the form: `instruction operand1, operand2`. There are three options for operands:

- **Immediate**: constant integer data (e.g. `$0x400`, `-$533`) or an address/label (e.g. `Loop`, `main`)
- **Register**: use the data stored in one of the 16 general purpose registers or subsets (e.g. `%rax`, `%edi`)
- **Memory**: use the data at the memory address specified by the addressing mode `D(Rb, Ri, S)`

The operation determines the effect of the operands on the processor state and has a suffix ("b" for byte, "w" for word, "l" for long, "q" for quad word) that determines the bit width of the operation. Sometimes the operation size can be inferred from the operands, so the suffix is omitted for brevity.

Control Flow and Condition Codes

Internally, condition codes (Carry, Zero, Sign, Overflow) are set based on the result of the previous operation. The `je*` and `set*` families of instructions use the values of these "flags" to determine their effects. See the table provided on your reference sheet for equivalent conditionals.

An *indirect jump* is specified by adding an asterisk (*) in front of a memory operand and causes your program counter to load the address stored at the computed address (e.g. `jmp *%rax`). This is useful for switch case statements.

| x86 instructions | English equivalent |
|---------------------------------------|---|
| <code>movq \$351, %rax</code> | Move the number 351 into 8-byte (quad) register "rax" |
| <code>addq %rdi, %rsi</code> | |
| <code>movq (%rdi), %r8</code> | |
| <code>leaq (%rax,%rax,8), %rax</code> | |

Exercises:

1. [CSE351 Au14 Midterm] Symbolically, what does the following code return?

```
movl  (%rdi), %eax          # %rdi -> x
leal  (%eax,%eax,2), %eax   # %rax -> r
addl  %eax, %eax
andl  %esi, %eax           # %rsi -> y
subl  %esi, %eax
ret
```

2. [CSE351 Au15 Midterm] Convert the following C function into x86-64 assembly code. You are not being judged on the efficiency of your code – just the correctness.

```
long happy(long *x, long y, long z) {
    if (y > z)
        return z + y;
    else
        return *x;
}
```

3. Write an equivalent C function for the following x86-64 code:

```
mystery:
    testl  %edx, %edx
    js     .L3
    cmpl  %esi, %edx
    jge   .L3
    movslq %edx, %rdx
    movl  (%rdi,%rdx,4), %eax
    ret
.L3:
    movl  $0, %eax
    ret
```
