Write a mathematical model of the following code:

```java
for (int i = 0; i < n; i++) {
    for (int j = 0; j < i; j++) {
        System.out.println("Hello!");
    }
}
```

Which of the following is a mathematical model for the runtime of the code given?

a.) $f(n) = 2n$

b.) $f(n) = n + n$

c.) $f(n) = n^2$

d.) $f(n) = \sum_{i=n}^{n-1} \sum_{j=0}^{i-1} 1$
Modeling Complex Loops

```java
for (int i = 0; i < n; i++) {
    for (int j = 0; j < i; j++) {
        System.out.print("Hello! ");
    }
    System.out.println();
}
```

\[
T(n) = (0 + 1 + 2 + 3 + ... + i-1)
\]

How do we model this part?

Summations!

\[
1 + 2 + 3 + 4 + ... + \sum_{i=1}^{n}
\]

\[
T(n) = \sum_{i=0}^{n-1} \sum_{j=0}^{i-1} 1
\]

What is the Big O?

Definition: Summation

\[
\sum_{i=a}^{b} f(i) = f(a) + f(a + 1) + f(a + 2) + ... + f(b-2) + f(b-1) + f(b)
\]
Simplifying Summations

for (int i = 0; i < n; i++) {
    for (int j = 0; j < i; j++) {
        System.out.println("Hello!");
    }
}

\[ T(n) = \sum_{i=0}^{n-1} \sum_{j=0}^{i-1} 1 = \sum_{i=0}^{n-1} 1 \cdot i = 1 \sum_{i=0}^{n-1} i = \frac{n(n-1)}{2} = \frac{1}{2} n^2 - \frac{1}{2} n = O(n^2) \]

**Summation of a constant**
\[ \sum_{i=0}^{n-1} c = cn \]

**Factoring out a constant**
\[ \sum_{i=a}^{b} cf(i) = c \sum_{i=a}^{b} f(i) \]

**Gauss’s Identity**
\[ \sum_{i=0}^{n-1} i = \frac{n(n-1)}{2} \]
Traversing Data

Array
for (int i = 0; i < arr.length; i++) {
    System.out.println(arr[i]);
}

List
for (int i = 0; i < myList.size(); i++) {
    System.out.println(myList.get(i));
}

for (T item : list) {
    System.out.println(item);
}
Review: Iterators

**iterator**: a Java interface that dictates how a collection of data should be traversed. Can only move in the forward direction and in a single pass.

---

**Supported operations:**

**hasNext()** – returns true if the iteration has more elements yet to be examined

**next()** – returns the next element in the iteration and moves the iterator forward to next item

```java
ArrayList<Integer> list = new ArrayList<Integer>(); //fill up list
Iterator itr = list.iterator();
while (itr.hasNext()) {
    int item = itr.next();
}
```

---

**Iterator Interface**

<table>
<thead>
<tr>
<th>behavior</th>
<th>supported operations</th>
</tr>
</thead>
<tbody>
<tr>
<td>hasNext()</td>
<td>returns true if elements remain</td>
</tr>
<tr>
<td>next()</td>
<td>returns next element</td>
</tr>
</tbody>
</table>

---

```java
ArrayList<Integer> list = new ArrayList<Integer>(); //fill up list
for (int i : list) { int item = i; }
```
Implementing an Iterator

**hasNext()**

```
front -> itr
```

```
front -> itr
```

Result

- true
- false

**next()**

```
front -> itr
```

```
front -> itr
```

```
front -> itr
```

```
front -> itr
```

Result

- 4

Project 2 out today
- Due Wednesday April 28th

Exercise 2 out today
- Due Friday April 23rd
Questions
Roadmap for lecture content today

- Maps/Dictionary review
- DirectAccessMap
  - a map implemented with an array with only integer keys
- SimpleHashMap
  - a more flexible version of DirectAccessMap that uses a hash function on the key of interest to figure out where it is in the array
- SeparateChainingHashMap
  - fixes some limitations of the above Maps while still being very fast (in-practice).
  - It’s what you’ll implement in project 2 / what Java’s official HashMap does -- it’s the back-bone data structure that powers so many Java programs and that you will definitely use if you keep programming. Get hyped!
Dictionaries (aka Maps)

Every Programmer’s Best Friend

You’ll probably use one in almost every programming project.
- Because it’s hard to make a big project without needing one sooner or later.

// two types of Map implementations supposedly covered in CSE 143
Map<String, Integer> map1 = new HashMap<>();
Map<String, String> map2 = new TreeMap<>();
**Review: Maps**

**map**: Holds a set of distinct *keys* and a collection of *values*, where each key is associated with one value.
- a.k.a. "dictionary"

**Dictionary ADT**

**state**
- Set of items & keys
- Count of items

**behavior**
- put(key, item): add item to collection indexed with key
  - get(key) return item associated with key
  - containsKey(key) return if key already in use
- remove(key): remove item and associated key
- size(): return count of items

**supported operations:**
- put(key, value): Adds a given item into collection with associated key,
  - if the map previously had a mapping for the given key, old value is replaced.
- get(key): Retrieves the value mapped to the key
- containsKey(key): returns true if key is already associated with value in map, false otherwise
- remove(key): Removes the given key and its mapped value
Implementing a Map with an Array

Map ADT

**state**
Set of items & keys
Count of items

**behavior**
- **put(key, item)** add item to collection indexed with key
- **get(key)** return item associated with key
- **containsKey(key)** return if key already in use
- **remove(key)** remove item and associated key
- **size()** return count of items

containsKey(‘c’)
get(‘d’)
put(‘b’, 97)
put(‘e’, 20)

Big O Analysis – (if key is the last one looked at / not in the dictionary)

ArrayMap<K, V> - 

```java
ArrayMap<Pair<K, V>[] data
```

state
Pair<K, V>[] data

behavior
- put: find key, overwrite value if there. Otherwise create new pair, add to next available spot, grow array if necessary
- get: scan all pairs looking for given key, return associated item if found
- containsKey: scan all pairs, return if key is found
- remove: scan all pairs, replace pair to be removed with last pair in collection
- size: return count of items in dictionary

0 1 2 3 4

| ('a', 1) | ('b', 97) | ('c', 3) | ('d', 4) | ('e', 20) |
Implementing a Map with Nodes

Can we do better?

Let’s simplify the problem we’re working with + combine it with some facts about arrays.

- problem simplification: only worry about supporting integer keys
- array facts: accessing (data[i]) or updating an element (data[i] = ...) at a given index takes Theta(1) runtime.
- If we store the Key-Value pairs at the data[key] then we don’t have to do any looping to find it. For example consider `containsKey` or `get` -- we can just jump directly to data[key] to figure out the return answer.
Can we do better?

Let’s simplify the problem we’re working with + combine it with some facts about arrays.

- problem simplification: only worry about supporting integer keys
- array facts: accessing \( \text{data}[i] \) or updating an element \( \text{data}[i] = \ldots \) at a given index takes \( \Theta(1) \) runtime.

If we store the Key-Value pairs at the data[key] then we don’t have to do any looping to find it. For example consider 'containsKey' or 'get' -- we can just jump directly to data[key] to figure out the return answer.

```java
put(3, "Sherdil");
get(3);
```

</tr>
</tbody>
</table>
Direct Access Map tradeoffs:

- what’s a benefit of using DirectAccessMap?
- what’s a bad thing when using DirectAccessMap?

- 😞 wasted space
  - what if we want to store two key: 0 and 99999999999? Our current setup would just be wasting all that array space in-between

- 😞 only integer keys
  - kind of annoying that we could only have this for ints, but **being able to quickly go from the key to the array index is super valuable because it's array lookups are fast (constant time)**. When we can just jump to the right position, we avoid the looping that ArrayMap/LinkedMap had to do where you might have to loop and look at every element. We’ll keep this core idea of “knowing the index” and jumping there right away for all the versions of the dictionaries we talk about today.

- 😊 super fast though: Θ(1) runtime for everything
Can we do this for any integer?

Idea 1:
Create a GIANT array with every possible integer as an index

Problems:
- Can we allocate an array big enough?
- Super wasteful

Idea 2:
Create a smaller array, but create a way to translate given integer keys into available indices. Way less wasteful space-wise.

Problem:
- How can we pick a good translation?
Hash functions: translating a piece of data to an int

<table>
<thead>
<tr>
<th>Hash function definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>A <strong>hash function</strong> is any <strong>function</strong> that can be used to map <strong>data</strong> of arbitrary size to fixed-size values.</td>
</tr>
</tbody>
</table>

In our case: we want to translate int keys to a valid index in our array. If our array is length 10 but our input key is 500, we need to make sure we have a way of mapping that to a number between 0 and 9 (the valid indices for a length 10 array). This mapping that we decide on is a **hash function**.

One simple thing we can do (and that you will do when you implement this in your project):

- **Hash function:** take your key and % it by the length of the array.
- **ex:** key is 500, and array is length 10 – if you take 500 % 10, you will get the number 0, so we’d just plop 500 and it’s value at index 0.
“review”: Integer remainder with % “mod”

The % operator computes the remainder from integer division.

\[
\begin{array}{c}
14 \div 4 = 3 \\
4 \quad \underline{14} \\
\quad 12 \\
\hline
\quad 2
\end{array}
\qquad
\begin{array}{c}
218 \div 5 = 43 \\
5 \quad \underline{218} \\
\quad 20 \\
\quad 18 \\
\hline
\quad 3
\end{array}
\]

Equivalently, to find \(a \% b\) (for \(a, b > 0\)):

\[
\text{while}(a > b-1) \\
\text{\quad a -= b;}
\]

\text{return a;}

Applications of % operator:

- Obtain last digit of a number: \(230857 \% 10\) is 7
- See whether a number is odd: \(7 \% 2\) is 1, \(42 \% 2\) is 0
- Limit integers to specific range: \(8 \% 12\) is 8, \(18 \% 12\) is 6

Limit keys to indices within array

For more review/practice, check out [https://www.khanacademy.org/computing/computer-science/cryptography/modarithmetic/a/what-is-modular-arithmetic](https://www.khanacademy.org/computing/computer-science/cryptography/modarithmetic/a/what-is-modular-arithmetic)
First Hash Function: % table size

---

**Collision!**
Hash Obsession: Collisions

Collision: multiple keys translate to the same location of the array

Future big idea: the fewer the collisions, the better the runtime! (we’ll see this when we figure out that resolving these leads to worse runtime)

Two questions:
1. When we have a collision, how do we resolve it?
2. How do we minimize the number of collisions?
Roadmap for lecture content today

- Maps/Dictionary review
- DirectAccessMap
  - a map implemented with an array with only integer keys
- SimpleHashMap
  - a more flexible version of DirectAccessMap that uses a hash function on the key of interest to figure out where it is in the array
- SeparateChainingHashMap
  - fixes some limitations of the above Maps while still being very fast (in-practice).
  - It’s what you’ll implement in project 2 / what Java’s official HashMap does -- it’s the back-bone data structure that powers so many Java programs and that you will definitely use if you keep programming. Get hyped!
Strategies to handle hash collision

There are multiple strategies. In this class, we’ll cover the following ones:

1. Separate chaining
2. Open addressing
   - Linear probing
   - Quadratic probing
   - Double hashing
Separate chaining

Solution 1: Separate Chaining

Each index in our array represents a “bucket”. When an item $x$ hashes to index $h$:
- If the bucket at index $h$ is empty: create a new list containing $x$
- If the bucket at index $h$ is already a list: add $x$ if it is not already present

In other words:

If multiple things hash to the same index, then we’ll just put all of those in that same index bucket. Often, you’ll see the data structure chosen is a linked-list like structure.
Separate chaining

// some pseudocode
public boolean containsKey(int key) {
    int bucketIndex = key % data.length;
    loop through data[bucketIndex]
        return true if we find the key in
        data[bucketIndex]
    return false if we get to here (didn’t
    find it)
}

Reminder: the implementations of put/get/containsKey are all very similar, and almost always will have the same complexity class runtime

Yes! If we had to do a lot of loop iterations to find the key in the bucket, our code will run slower.
A best case situation for separate chaining

It’s possible (and likely if you follow some best-practices) that everything is spread out across the buckets pretty evenly. This is the opposite of the last slide: when we have minimal collisions, our runtime should be less. For example, if we have a bucket with only 0 or 1 element in it, checking `containsKey` for something in that bucket will only take a constant amount of time.

We’re going to try a lot of stuff we can to make it more likely we achieve this beautiful state 😊.
In-practice situations for separate chaining

Generally we can achieve something close to the best case situation from the previous slide and maintain our Hash Map so that every bucket only has a small constant number of items. There may be some outliers that have slightly more buckets, but generally if we follow all the best practices, the runtime will still be $\Theta(1)$ for most cases!

(The worst case is still $\Theta(n)$ but again, we’ll try really hard to prevent that)

<table>
<thead>
<tr>
<th>Operation</th>
<th>Array w/ indices as keys</th>
</tr>
</thead>
<tbody>
<tr>
<td>put(key,value)</td>
<td>best: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>In-practice: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>worst: $\Theta(n)$</td>
</tr>
<tr>
<td>get(key)</td>
<td>best: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>In-practice: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>worst: $\Theta(1)$</td>
</tr>
<tr>
<td>remove(key)</td>
<td>best: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>In-practice: $\Theta(1)$</td>
</tr>
<tr>
<td></td>
<td>worst: $O(n)$</td>
</tr>
</tbody>
</table>

Reminder: the in-practice runtimes are assuming an even distribution of the keys inside the array and following of best-practices to ensure the average chain length is low.
Best practices (pay attention to this for the hw)

- what about resizing?
- for data structures like ArrayMap or ArrayList or ArrayStack we had to resize when we’re full just because we couldn’t store any more things! But our Separate Chaining Hash Map is a little bit different: we aren’t ever forced to resize our main array, since the buckets are flexible size.

It turns out we still want to resize “every so often” to make sure the average/expected length of each bucket is a small number.

Consider what happens if we had the array length 10 like on the left, but had 100 key-value pairs?

Assuming our in-practice niceness (not-worst case) you would expect on average each of the 10 buckets has about 10 key-value pairs in it.

What happens if we stick with the same size array but add 100 more key-value pairs? Each bucket gets about 10 more –key-value pairs and the runtime is getting worse and worse.
Best practices (pay attention to this for the hw)

It turns out we still want to resize “every so often” to make sure the average/expected length of each bucket is a small number.

Consider what happens if we had the array length 10 like on the left, but had 100 key-value pairs?

Assuming our in-practice niceness (not-worst case) you would expect on average each of the 10 buckets has about 10 key-value pairs in it.

What happens if we stick with the same size array but add 100 more key-value pairs? Each bucket gets about 10 more –key-value pairs and the runtime is getting worse and worse.

The pattern we’re getting to is that the expected runtime is approximately: \# of pairs / array.length (AKA n / c where n is the number of elements and c is the number of possible chains). If array.length is fixed for your whole program, then this is an order-n runtime, but if the array.length also increases (because you re-size) and you redistribute out the values evenly across the buckets, you can keep your runtime low. In particular, if you resize when when your n / c ratio increases to about 1, you’re expected to have 1 element or fewer in each bucket at all times. (do this on your homework).

Tip: make sure you re-hash (re-distribute) your keys by the new array length after re-sizing so they don’t get clustered in the old array length range.
Lambda + resizing rephrased

To be more precise, the in-practice runtime depends on $\lambda$, the current average chain length.

However, if you resize once you hit that 1:1 threshold, the current $\lambda$ is expected to be less than 1 (which is a constant / constant runtime, so we can simplify to $O(1)$).

<table>
<thead>
<tr>
<th>Operation</th>
<th>Array w/ indices as keys</th>
</tr>
</thead>
<tbody>
<tr>
<td>put(key,value)</td>
<td>best $O(1)$</td>
</tr>
<tr>
<td>get(key)</td>
<td>best $O(1)$</td>
</tr>
<tr>
<td>remove(key)</td>
<td>best $O(1)$</td>
</tr>
</tbody>
</table>

“In-Practice” Case:
Depends on average number of elements per chain

Load Factor $\lambda$
If $n$ is the total number of key-value pairs
Let $c$ be the capacity of array
Load Factor $\lambda = \frac{n}{c}$
What about non integer keys?

<table>
<thead>
<tr>
<th>Hash function definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>A <strong>hash function</strong> is any <strong>function</strong> that can be used to map <strong>data</strong> of arbitrary size to fixed-size values.</td>
</tr>
</tbody>
</table>

Let’s use define another hash function to change stuff like Strings into ints!

**Best practices for designing hash functions:**

Avoid collisions
- The more collisions, the further we move away from $O(1+\lambda)$
- Produce a wide range of indices, and distribute evenly over them

Low computational costs
- Hash function is called every time we want to interact with the data
(Before we % by length, we have to convert the data into an int)

Implementation 1: Simple aspect of values
public int hashCode(String input) {
    return input.length();
}

Implementation 2: More aspects of value
public int hashCode(String input) {
    int output = 0;
    for(char c : input) {
        out += (int)c;
    }
    return output;
}

Implementation 3: Multiple aspects of value + math!
public int hashCode(String input) {
    int output = 1;
    for (char c : input) {
        int nextPrime = getNextPrime();
        out *= Math.pow(nextPrime, (int)c);
    }
    return Math.pow(nextPrime, input.length());
}
Java’s hashCode (relevant for project)

- Luckily, most of these design decisions have been made for us by smart people. All objects in Java come with a `hashCode()` method that does some magic (see previous slide for the not-magic version) to turn any object type (like String, ArrayList, Point, Scanner) into an integer. These hashes are designed to distribute pretty evenly / not have lots of collisions, so we use them as the starting point for determining the bucket index.

- High level steps to figure out which bucket a key goes into
  - call the key.hashCode() to get an int representation of the object
  - % by the array table length to convert it to a valid index for your hash map
Best practices for an nice distribution of keys recap

- resize when lambda (number of elements / number of buckets) increases up to 1
- when you resize, you can choose a the table length that will help reduce collisions if you multiply the array length by 2 and then choose the nearest prime number
- design the hashCode of your keys to be somewhat complex and lead to a distribution of different output numbers
Consider an IntegerDictionary using separate chaining with an internal capacity of 10. Assume our buckets are implemented using a LinkedList where we append new key-value pairs to the end.

Now, suppose we insert the following key-value pairs. What does the dictionary internally look like?

(1, a) (5, b) (11, a) (7, d) (12, e) (17, f) (1, g) (25, h)
Consider a `StringDictionary` using separate chaining with an internal capacity of 10. Assume our buckets are implemented using a `LinkedList`. Use the following hash function:

```java
public int hashCode(String input) {
    return input.length() % arr.length;
}
```

Now, insert the following key-value pairs. What does the dictionary internally look like?

- (“a”, 1)
- (“ab”, 2)
- (“c”, 3)
- (“abc”, 4)
- (“abcd”, 5)
- (“abcdabcd”, 6)
- (“five”, 7)
- (“hello world”, 8)
Java and Hash Functions

Object class includes default functionality:
- equals
- hashCode

If you want to implement your own hashCode you should:
- Override BOTH hashCode() and equals()

If a.equals(b) is true then a.hashCode() == b.hashCode() MUST also be true

That requirement is part of the Object interface. Other people’s code will assume you’ve followed this rule.

Java’s HashMap (and HashSet) will assume you follow these rules and conventions for your custom objects if you want to use your custom objects as keys.
