

Input-output

- I/O is very much architecture/system dependent
- I/O requires cooperation between
 - **processor** that issues I/O command (read, write etc.)
 - **buses** that provide the interconnection between processor, memory and I/O devices
 - **I/O controllers** that handle the specifics of control of each device and interfacing
 - **devices** that store data or signal events

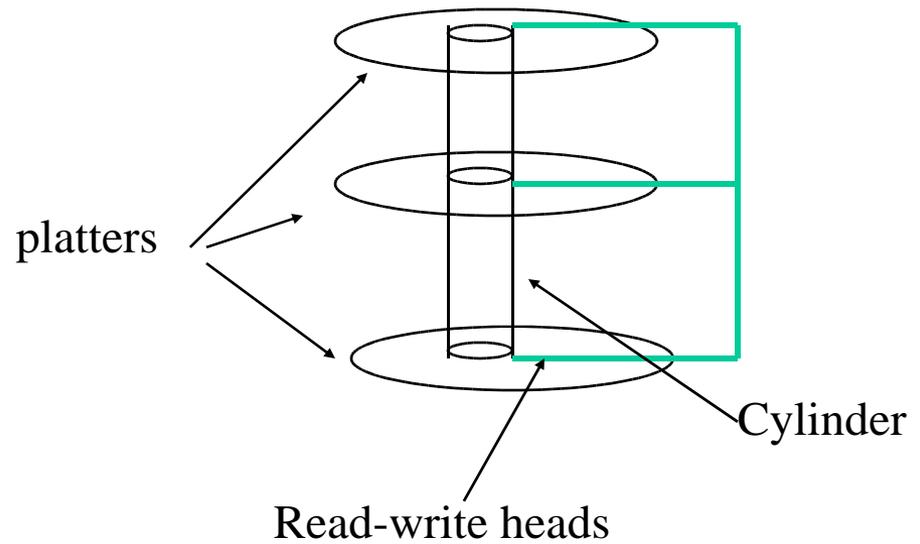

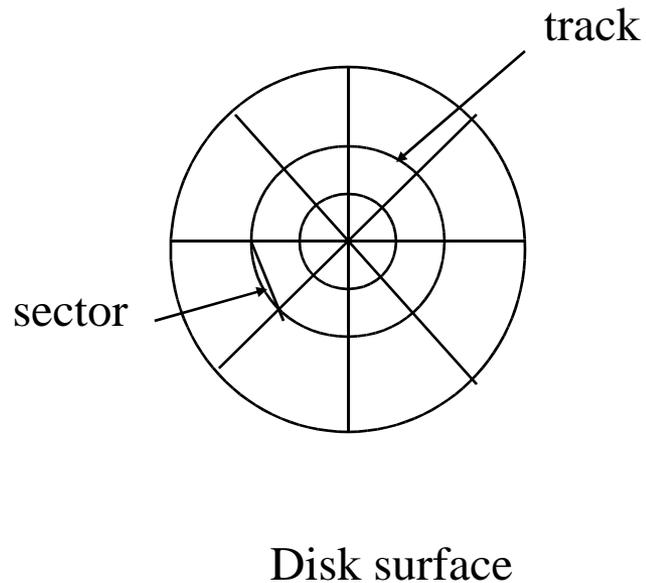

Basic (simplified) I/O architecture

Types of I/O devices

- Input devices
 - keyboard, mouse
- Output devices
 - screen, line printer
- Devices for both input and output
 - disks, network interfaces

An important I/O device: the disk

Secondary memory (disks)

- Physical characteristics
 - **Platters** (1 to 20) with diameters from 1.3 to 8 inches (recording on both sides)
 - **Tracks** (1,000 to 10,000)
 - **Cylinders** (all the tracks in the same position in the platters)
 - **Sectors** (e.g., 128-256 sectors/track with gaps and info related to sectors between them; typical sector 512 bytes)
 - Current trend: constant bit density, i.e., more info (sectors) on outer tracks

Example: IBM Ultrastar 146Z10

- Disk for server
 - 146 GB
 - 8 MB cache
 - 10,000 RPM
 - 3 ms average latency
 - Up to 6 platters; Up to 12 heads
 - Average seek latency 4.7 ms
 - Sustained transfer rate 33-66 MB/s

Disk access time

- Arm(s) with a reading/writing head
- Four components in an access:
 - **Seek time** (to move the arm on the right cylinder). From 0 (if arm already positioned) to a maximum of 15-20 ms. Not a linear function. Smaller disks have smaller seek times.
Ultrastar example: Average seek time = 4.7 ms;
 - My guess: track to track 0.5 ms; longest (inmost track to outmost track) 8 ms
 - **Rotation time** (on the average 1/2 rotation). At 3600 RPM, 8.3 ms. Current disks are 3600 or 5400 or 7200 or even 10,000 RPM (e.g., the Ultrastar, hence average is 3 ms)

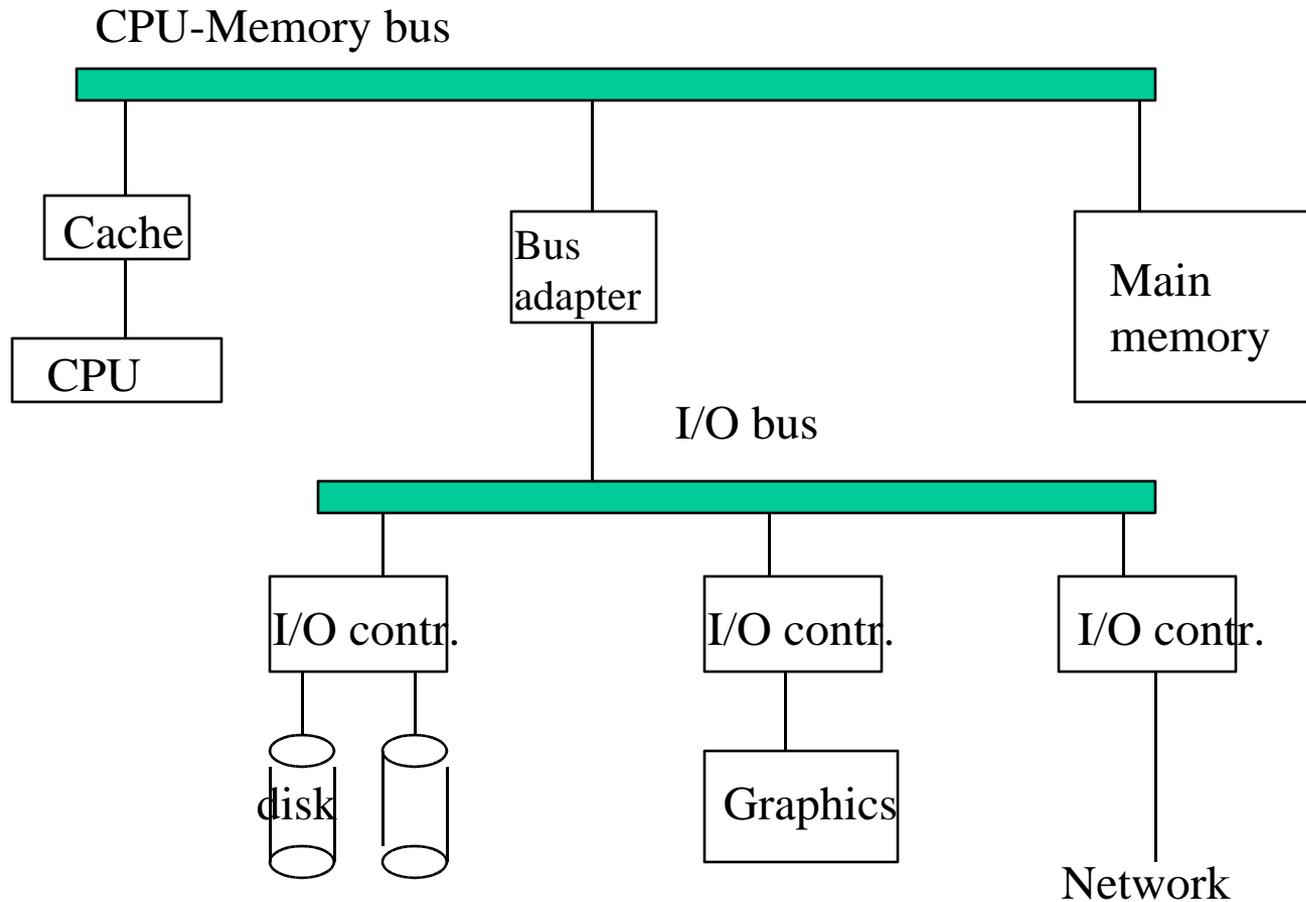

Disk access time (ct'd)

- **Transfer time** depends on rotation time, amount to transfer (minimal size a sector), recording density, disk/memory connection. Today, transfer time occurs at 6 to 66 MB/second
- **Disk controller time**. Overhead to perform an access (of the order of 1 ms)
- But ... many disk controllers have a cache that contains recently accessed sectors. If the I/O requests hits in the cache, the only components of access time are disk controller time and transfer time (which is then of the order of 40 MB/sec). Cache is used to prefetch on read.

Improvements in disks

- Capacity (via density). Same growth rate as DRAMs
- Price decrease has followed (today \$5-\$50/GB?)
- Access times have decreased but not enormously
 - Higher density -> smaller drives -> smaller seek time
 - RPM has increased slightly 3600 upto 10,000 (rarely)
 - Transfer time has improved
- CPU speed - DRAM access is one “memory wall”
- DRAM access time - Disk access time is a “memory gap”
 - Technologies to fill the gap have not succeeded (currently the most promising is more DRAM backed up by batteries)

Connecting CPU, Memory and I/O

Buses

- Simplest interconnect
 - **Low cost**: set of shared wires
 - **Easy to add devices** (although variety of devices might make the design more complex or less efficient -- longer bus and more electrical load; hence the distinction between I/O buses and CPU/memory buses)
 - But bus is a single shared resource so **can get saturated** (both physically because of electrical load, and performance-wise because of contention to access it)
- Key parameters:
 - **Width** (number of lines:data, addresses, control)
 - **Speed** (limited by length and electrical load)

Memory and I/O buses

- **CPU/memory bus**: tailored to the particular CPU
 - **Fast** (separate address and data lines; of course separate control lines)
 - Often short and hence **synchronous** (governed by a clock)
 - **Wide** (64-128 and even 256 bits)
 - Expensive
- **I/O bus**: follows some standard so many types of devices can be hooked on to it
 - **Asynchronous** (hand-shaking protocol)
 - **Narrower**

Bus transactions

- Consists of **arbitration** and **commands**
 - Arbitration: who is getting control of the bus
 - Commands: type of transaction (read, write, ack, etc...)
- Read, Write, Atomic Read-Modify-Write (atomic swap)
 - **Read**: send address and data is returned
 - **Write**: send address and data
 - **Read-Modify-write** : keep bus during the whole transaction. Used for synchronization between processes

Bus arbitration

- Arbitration: who gets the bus if several requests occur at the same time
 - Only one master (processor): centralized arbitration
 - Multiple masters (most common case): **centralized** arbitration (FIFO, daisy-chain, round-robin, combination of those) vs. **decentralized** arbitration (each device knows its own priority)
- Communication protocol between master and slave
 - **Synchronous** (for short buses - no clock skew - i.e. CPU/memory)
 - **Asynchronous** (hand-shaking finite-state machine; easier to accommodate many devices)

Hand-shaking protocol

- Example : Master (CPU) requests data from Slave (Mem)
 1. Master transmits a **read request** (control lines) and address (address/data lines)
 2. Slave recognizes the request. Grabs the address and raises the **Ack** control line.
 3. Master sees the Ack line high. Releases the **request** and data lines
 4. Slave sees the Read request low. Releases the **Ack** line
 5. Slave is ready to transmit data. Places data on data lines and raises **Data ready** (control line)
 6. Master sees Data ready high. Grabs data and raises **Ack**
 7. Slave sees Ack high. Releases data line and **Data Ready**
 8. Master sees Data Ready low. Releases **Ack**. Transaction is finished

Split-transaction buses

- Split a read transaction into
 - Send address (CPU is master)
 - Send data (Memory is master)
 - In between these two transactions (memory access time) the bus is freed
 - Requires “tagging” the transaction
- Can even have more concurrency by having different transactions using the data and address lines concurrently
- Useful for multiprocessor systems and for I/O

I/O Hardware-software interface

- I/O is best left to the O.S. (for protection and scheduling in particular)
- O.S. provides routines that handles devices (or controllers)
- But since O.S. is a program, there must be instructions to generate I/O commands
- CPU must be able to:
 - tell a device what it wants done (e.g., read, write, etc.)
 - start the operation (or tell the device controller to start it)
 - find out when the operation is completed (with or without error)
- No unique way to do all this. Depends on ISA and I/O architecture

I/O operations

- Specific I/O instructions
 - I/O instruction specifies both the device number and a command (or an address where the I/O device can find a series of commands)
Example: Intel x86 (IN and OUT between EAX register and an I/O port whose address is either an immediate or in the DX register)
- Memory-mapped I/O
 - Portions of address space devoted to I/O devices (read/write to these addresses transfer data or are used to control I/O devices)
 - Memory ignores these addresses
- In both cases, only the O.S. can execute I/O operations or read/write data to memory-mapped locations

I/O termination

- Two techniques to know when an I/O operation terminates
 - Polling
 - Interrupts
- Polling
 - CPU repeatedly checks whether a device has completed
 - Used for “slow” devices such as the mouse (30 times a second)
- Interrupts
 - When the I/O completes it generates an (I/O) interrupt

I/O interrupts

- An interrupt is like an exception
 - Exception created by the program (page fault, divide by zero etc.)
 - Interrupts occur as a consequence of external stimuli (I/O, power failure etc.)
- Presence of an interrupt checked on every cycle
- Upon an interrupt, O.S. takes over (context-switch)
- Two basic schemes to handle the interrupt
 - *Vectored* interrupts: the O.S. is told (by the hardware) where to handle the interrupt
 - Use of a *cause register*. The O.S. has to examine the contents of that register to transfer to the appropriate handler

Data transfer to/from I/O device

- Can be done either by
 - Using the CPU to transfer data from (to) the device to (from) memory.
 - Can be done either via polling (*programmed I/O operation*) or interrupt
 - Slow operation
 - Using **DMA** (direct-memory address)

DMA

- Having long blocks of I/O go through the processor via load-store is totally inefficient
- DMA (direct memory address) controller:
 - specialized processor for transfer of blocks between memory and I/O devices w/o intervention from CPU (except at beg. and end)
 - Has registers set up by CPU for beginning memory address and count
 - DMA device interrupts CPU at end of transfer
 - DMA device is a master for the bus
 - More complex DMA devices become I/O processors or channels controllers (with their own stored programs)

DMA and virtual memory

- What if the block to transfer is greater than 1 page
 - Address translation registers within the DMA device
- What if the O.S. replaces a page where transfer is taking place
 - Pages are “pinned” (locked) during transfer

I/O and caches

- Recall previous discussion
 - Write-back caches:
 - on output, the O.S. flushes the cache before the page is written out
 - on input, blocks in the cache are invalidated
 - Write-through caches
 - on output, no problem since cache and memory are consistent
 - on input, as in write-back
- Other possibilities
 - Use a “snoopy” protocol (cache controller listen to transactions on the memory bus and reacts accordingly)
 - Have the I/O go through the cache (but not very efficient)

Disk arrays

- Reliability: is anything broken?
- Availability: is the system still usable?
- Availability can be improved by adding more hardware (e. g., ECC, disk arrays) that provides some redundancy
- In the case of I/O, simplest redundant system is *mirroring*: write each data on two disks.
 - Cost: double the amount of hardware
 - Performance: no increase (in fact might be worse for writes since has to wait for the longest of the two to complete)

RAIDs

- Concept of *striping*: data written consecutively on N disks
- Performance wise: no improvement in latency but improvement in throughput (parallelism)
- But now probability of failure is greater
- So add disks (redundant arrays of inexpensive disks)
 - Mirroring = RAID1
 - RAID 5: interleave the parity sectors on the disks
