Polynomial Time
Why big-O: measuring algorithm efficiency
What is the $n^{th}$ prime number?

Let $p_n = n^{th}$ prime, $n \geq 1$, e.g.:

$p_1 = 2$
$p_2 = 3$
$p_3 = 5$
$p_4 = 7$
$p_5 = 11$

After much study, we know $p_n \sim n \log n$, even:

$$\frac{p_n}{n} = \log n + \log \log n - 1 + \frac{\log \log n - 2}{\log n} - \frac{(\log \log n)^2 - 6 \log \log n + 11}{2(\log n)^2} + o \left( \frac{1}{(\log n)^2} \right)$$

Great precision! But, often a simple, smooth, upper bound, is even better, e.g.: $p_n = O(n \log n)$

[https://en.wikipedia.org/wiki/Prime_number_theorem](https://en.wikipedia.org/wiki/Prime_number_theorem)
Our correct TSP algorithm was incredibly slow
  No matter what computer you have
As a 2\textsuperscript{nd} example, for large problems, mergesort
beats insertion sort – \( n \log n \) vs \( n^2 \) matters a lot
  Even tho the alg is more complex & inner loop is slower
No matter what computer you have
We want a general theory of “efficiency” that is
  Simple
  Objective
  Relatively independent of changing technology
Measures \textit{algorithm}, not code
But still \textit{predictive} – “theoretically bad” algorithms should
be bad in practice and vice versa (usually)
The time complexity of an algorithm associates a number $T(n)$, the worst-case time the algorithm takes, with each problem size $n$.

Mathematically,

$T: \mathbb{N}^+ \rightarrow \mathbb{R}$

i.e., $T$ is a function mapping positive integers (problem sizes) to positive real numbers (number of steps).

“Reals” so, e.g., we can say $\sqrt{n}$ instead of $\lceil \sqrt{n} \rceil$

“Positive” so, e.g., $\log(n)$ and $2^n/n$ aren’t problematic
computational complexity

Problem size vs. Time

$T(n)$
computational complexity: general goals

Asymptotic growth rate, i.e., characterize growth rate of worst-case run time as a function of problem size, up to a constant factor, e.g. \( T(n) = O(n^2) \)

Why not try to be more precise?

Average-case, e.g., is hard to define, analyze
Technological variations (computer, compiler, OS, …) easily 10x or more
Being more precise is much more work

A key question is “scale up”: if I can afford this today, how much longer will it take when my business is 2x larger? (E.g. today: \( cn^2 \), next year: \( c(2n)^2 = 4cn^2 \) : 4 x longer.) Big-O analysis is adequate to address this.
What’s big-O: definition and related concepts
Given two functions $f$ and $g$: $\mathbb{N}^+ \rightarrow \mathbb{R}$

- $f(n)$ is $O(g(n))$ iff there is a constant $c > 0$ so that $f(n)$ is eventually always $\leq c \cdot g(n)$
  
- $f(n)$ is $\Omega(g(n))$ iff there is a constant $c > 0$ so that $f(n)$ is eventually always $\geq c \cdot g(n)$
  
- $f(n)$ is $\Theta(g(n))$ iff there are constants $c_1, c_2 > 0$ so that eventually always $c_1 g(n) \leq f(n) \leq c_2 g(n)$
  
“Eventually always $P(n)$” means “$\exists n_0 \text{ s.t. } \forall n > n_0 \ P(n)$ is true.” i.e., there can be exceptions, but only for finitely many “small” values of $n$. 

**Upper Bounds**

**Lower Bounds**

**Both**
computational complexity
Example: $T(n) = \Theta(n \log n)$ since for all problem sizes $n > n_0$, the worst case run time $T(n)$ is between $n \log_2 n$ and $2n \log_2 n$. 
A typical program with initialization and two nested loops might have runtime something like this.
If $T(n) = n^2 + 30n + 5000$, then $T(n) = \Theta(n^2)$, since for all $n \geq 135$, we have $n^2 \leq T(n) \leq 1.5 n^2$.
Reasoning with big-O: examples & applications

polynomials
exponentials
logarithms
sums
Show $10n^2 - 16n + 100$ is $O(n^2)$:

\[
10n^2 - 16n + 100 \leq 10n^2 + 100 = 10n^2 + 10^2 \\
\leq 10n^2 + n^2 = 11n^2 \text{ for all } n \geq 10
\]

\[\therefore O(n^2) \quad [\text{and also } O(n^3), O(n^4), O(n^{2.5}), \ldots ]\]
Show $10n^2 - 16n + 100$ is $\Omega(n^2)$:

$$10n^2 - 16n + 100 \geq 10n^2 - 16n \geq 10n^2 - n^2 = 9n^2 \text{ for all } n \geq 16$$

$\therefore \Omega(n^2)$ [and also $\Omega(n)$, $\Omega(n^{1.5})$, …]

Therefore also $10n^2 - 16n + 100$ is $\Theta(n^2)$

[but not $\Theta(n^{1.999})$ or $\Theta(n^{2.001})$]
Polynomials:
\[ p(n) = a_0 + a_1 n + \ldots + a_d n^d \] is \( \Theta(n^d) \) if \( a_d > 0 \)

Proof:
\[
\begin{align*}
p(n) &= a_0 + a_1 n + \ldots + a_d n^d \\
&\leq |a_0| + |a_1| n + \ldots + a_d n^d \\
&\leq |a_0| n^d + |a_1| n^d + \ldots + a_d n^d \quad \text{(for } n \geq 1) \\
&= c n^d, \text{ where } c = (|a_0| + |a_1| + \ldots + |a_{d-1}| + a_d) \\
\therefore \quad p(n) &= O(n^d)
\end{align*}
\]

Exercise: show that \( p(n) = \Omega(n^d) \)

Hint: this direction is trickier; focus on the “worst case” where all coefficients except \( a_d \) are negative.
another example of working with \( O - \Omega - \Theta \) notation

Example: For any \( a \), and any \( b > 0 \), \((n+a)^b\) is \( \Theta(n^b) \)

\[
(n+a)^b \leq (2n)^b \quad \text{for } n \geq |a|
\]
\[
= 2^b n^b
\]
\[
= c n^b \quad \text{for } c = 2^b
\]
so \((n+a)^b\) is \( O(n^b) \)

\[
(n+a)^b \geq (n/2)^b \quad \text{for } n \geq 2|a| \text{ (even if } a < 0)\]
\[
= 2^{-b} n^b
\]
\[
= c'n \quad \text{for } c' = 2^{-b}
\]
so \((n+a)^b\) is \( \Omega(n^b) \)
Example: \( \sum_{1 \leq i \leq n} i = \Theta(n^2) \)

Proof:

(a) An upper bound: each term is \( \leq \) the max term

\[
\sum_{1 \leq i \leq n} i \leq \sum_{1 \leq i \leq n} n = n^2 = O(n^2)
\]

(b) A lower bound: each term is \( \geq \) the min term

\[
\sum_{1 \leq i \leq n} i \geq \sum_{1 \leq i \leq n} 1 = n = \Omega(n)
\]

This is valid, but a weak bound.

Better: pick a large subset of large terms

\[
\sum_{1 \leq i \leq n} i \geq \sum_{n/2 \leq i \leq n} n/2 \geq \left\lfloor n/2 \right\rfloor^2 = \Omega(n^2)
\]
Transitivity.
If \( f = O(g) \) and \( g = O(h) \) then \( f = O(h) \).
If \( f = \Omega(g) \) and \( g = \Omega(h) \) then \( f = \Omega(h) \).
If \( f = \Theta(g) \) and \( g = \Theta(h) \) then \( f = \Theta(h) \).

Additivity.
If \( f = O(h) \) and \( g = O(h) \) then \( f + g = O(h) \).
If \( f = \Omega(h) \) and \( g = \Omega(h) \) then \( f + g = \Omega(h) \).
If \( f = \Theta(h) \) and \( g = O(h) \) then \( f + g = \Theta(h) \).

Proofs are left as exercises.
For all \( r > 1 \) (no matter how small) and all \( d > 0 \), (no matter how large) \( n^d = O(r^n) \)

In short, every exponential grows faster than every polynomial!

(To prove this, use calculus tricks like L’Hospital’s rule.)
Example: For any \(a, b > 1\) \(\log_a n\) is \(\Theta(\log_b n)\)

\[
\log_a b = x \text{ means } a^x = b \quad \text{definition}
\]

\[
a^{\log_a b} = b
\]

\[
(a^{\log_a b})^{\log_b n} = b^{\log_b n} = n
\]

\[
(\log_a b)(\log_b n) = \log_a n
\]

\[
c \log_b n = \log_a n \text{ for the constant } c = \log_a b
\]

So:

\[
\log_b n = \Theta(\log_a n) = \Theta(\log n)
\]

Corollary: base of a log factor is usually irrelevant, asymptotically. E.g. “\(O(n \log n)\)” [but \(n^{\log_2 8} \neq O(n^{\log_8 8})\)]
Logarithms:

For all $x > 0$, (no matter how small) $\log n = O(n^x)$

log grows slower than every polynomial
big-theta, etc. are not always “nice”

\[ f(n) = \begin{cases} 
  n^2, & \text{n even} \\
  n, & \text{n odd} 
\end{cases} \]

\( f(n) \neq \Theta(n^a) \) for any \( a \).

Fortunately, such nasty cases are rare

\( n \log n \neq \Theta(n^a) \) for any \( a \), either, but at least it’s simpler.
Polynomial Time
the complexity class \( P: \) polynomial time

\( P: \) The set of problems solvable by algorithms with running time \( O(n^d) \) for some constant \( d \)

\( d \) is a constant independent of the input size \( n \)

**Nice scaling property:** there is a constant \( c \) s.t. doubling \( n \), time increases only by a factor of \( c \).

\( (E.g., \ c \sim 2^d) \)

Contrast with exponential: For any constant \( c \), there is a \( d \) such that \( n \rightarrow n+d \) increases time by a factor of more than \( c \).

\( (E.g., \ c = 100 \text{ and } d = 7 \text{ for } 2^n \text{ vs } 2^{n+7}) \)
polynomial vs exponential growth

- $2^{2n}$
- $2^{n/10}$
- $1000n^2$
why it matters

not only get very big, but do so abruptly, which likely yields erratic performance on small instances

Table 2.1 The running times (rounded up) of different algorithms on inputs of increasing size, for a processor performing a million high-level instructions per second. In cases where the running time exceeds $10^{25}$ years, we simply record the algorithm as taking a very long time.

</table>
why “polynomial”?

Point is not that $n^{2000}$ is a nice time bound, or that the differences among $n$ and $2n$ and $n^2$ are negligible.

Rather, simple theoretical tools may not easily capture such differences, whereas exponentials are qualitatively different from polynomials, so more amenable to theoretical analysis.

“My problem is in P” is a starting point for a more detailed analysis

“My problem is not in P” may suggest that you need to shift to a more tractable variant, or otherwise readjust expectations
Summary
A typical initial goal for algorithm analysis is to find a reasonably tight, asymptotic bound on worst case running time as a function of problem size. This is rarely the last word, but often helps separate good algorithms from blatantly poor ones – so you can concentrate on the good ones!

As one important example, poly time algorithms are almost always preferable to exponential time ones.
