2

How does OS handle a page fault?

- Interrupt causes system to be entered
- System saves state of running process, then vectors to page fault handler routine
 - find or create (through eviction) a page frame into which to load the needed page (1)
 - if I/O is required, run some other process while it's going on
 - find the needed page on disk and bring it into the page frame (2)
 - run some other process while the I/O is going on
 - fix up the page table entry
 - mark it as "valid," set "referenced" and "modified" bits to false, set protection bits appropriately, point to correct page frame
 - put the process on the ready queue

3

- (2) Find the needed page on disk and bring it into the page frame
 - processor makes process ID and faulting virtual address available to page fault handler
 - process ID gets you to the base of the page table
 - VPN portion of VA gets you to the PTE
 - PTE (or a parallel data structure) contains disk address of page
 - at this point, it's just a simple matter of I/O
 - must be positive that the target page frame remains available!
 - or what?

4

- (1) Find or create (through eviction) a page frame into which to load the needed page
 - run page replacement algorithm
 - free page frame
 - assigned but unmodified ("clean") page frame
 - assigned and modified ("dirty") page frame
 - assigned but "clean"
 - find PTE (may be a different process!)
 - mark as invalid (disk address must be available for subsequent reload)
 - assigned and "dirty"
 - find PTE (may be a different process!)
 - mark as invalid
 - write it out

5

"Issues"

- Memory reference overhead of address translation
 - 2 references per address lookup (page table, then memory)
 - solution: use a hardware cache to absorb page table lookups
 - translation lookaside buffer (TLB)
- Memory required to hold page tables can be huge
 - need one PTE per page in the virtual address space
 - 32 bit AS with 4KB pages = 2^{20} PTEs = 1,048,576 PTEs
 - 4 bytes/PTE = **4MB per page table**
 - OS's typically have separate page tables per process
 - 25 processes = 100MB of page tables
 - 48 bit AS, same assumptions, **64GB per page table!**
 - solution: page the page tables!
 - (ow, my brain hurts ...)

6

Paging the page tables 1

- Simplest notion:
 - put user page tables in a pageable segment of the system's address space
 - wire down the system's page table(s) in physical memory
 - allow the system segment containing the user page tables to be paged
 - a reference to a non-resident portion of a user page table is a page fault in the system address space
 - the system's page table is wired down
 - "no smoke and mirrors"
- As a practical matter, this simple notion doesn't cut the mustard today
 - although it is *exactly* what VAX/VMS did!
- But it's a useful model for what's actually done

7

Paging the page tables 2

- How can we reduce the physical memory requirements of page tables?
 - observation: only need to "actively" map the portion of the address space that is actually being used (often a tiny fraction of the total address space)
 - a process may not use its full 32/48/64-bit address space
 - a process may have unused "holes" in its address space
 - a process may not reference some parts of its address space for extended periods
 - all problems in CS can be solved with a level of indirection!
 - two-level (three-level, four-level) page tables

8

Two-level page tables

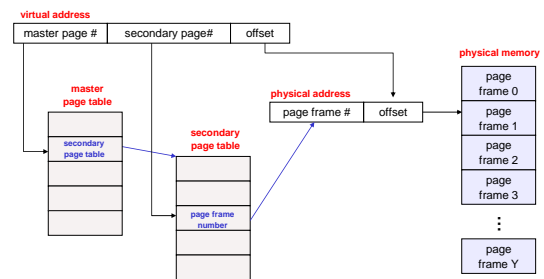

- With two-level PT's, virtual addresses have 3 parts:
 - master page number, secondary page number, offset
 - master PT maps master PN to secondary PT
 - secondary PT maps secondary PN to page frame number
 - offset and PFN yield physical address

9

Two level page tables

2/8/2004

© 2004 Ed Lazowska & Hank Levy

10

- Example:
 - 32-bit address space, 4KB pages, 4 bytes/PTE
 - how many bits in offset?
 - need 12 bits for 4KB, so offset is 12 bits
 - want master PT to fit in one page
 - 4KB/4 bytes = 1024 PTEs
 - so master page # is 10 bits
 - hence, there 1024 secondary page tables
 - and there are 10 bits are left for indexing each secondary page table
 - hence, each secondary page table has 1024 PTEs and fits in one page

11

Generalizing

- Early architectures used 1-level page tables
- VAX, P-II used 2-level page tables
- SPARC uses 3-level page tables
- 68030 uses 4-level page tables
- Key thing is that the outer level must be **wired down** (pinned in physical memory) in order to break the recursion – *no smoke and mirrors*

12

Alternatives

- Hashed page table (great for sparse address spaces)
 - VPN is used as a hash
 - collisions are resolved because the elements in the linked list at the hash index include the VPN as well as the PFN
- Inverted page table (really limits space!)
 - one entry per page frame
 - includes process id, VPN
 - hell to search! (but IBM PC/RT actually did this!)

13

TLB's: Making this mess efficient

- Original page table scheme doubled the cost of memory lookups
 - one lookup into page table, a second to fetch the data
- Two-level page tables triple the cost!!
 - two lookups into page table, a third to fetch the data
- How can we make this more efficient?
 - goal: make fetching from a virtual address about as efficient as fetching from a physical address
 - solution: use a hardware cache inside the CPU
 - cache the virtual-to-physical translations in the hardware
 - called a **translation lookaside buffer (TLB)**
 - TLB is managed by the memory management unit (MMU)

14

TLBs

- Translation lookaside buffers
 - translates virtual page #s into PTEs (**not** physical addr)
 - can be done in single machine cycle
- TLB is implemented in hardware
 - is a fully associative cache (all entries searched in parallel)
 - cache tags are virtual page numbers
 - cache values are PTEs
 - with PTE + offset, MMU can directly calculate the PA
- TLBs exploit locality
 - processes only use a handful of pages at a time
 - 16-48 entries in TLB is typical (64-192KB)
 - can hold the "hot set" or "working set" of a process
 - hit rates in the TLB are therefore really important

15

Managing TLBs

- Address translations are mostly handled by the TLB
 - >99% of translations, but there are **TLB misses** occasionally
 - in case of a miss, translation is placed into the TLB
- Hardware (memory management unit (MMU))
 - knows where page tables are in memory
 - OS maintains them, HW access them directly
 - tables have to be in HW-defined format
 - this is how x86 works
- Software loaded TLB (OS)
 - TLB miss faults to OS, OS finds right PTE and loads TLB
 - must be fast (but, 20-200 cycles typically)
 - CPU ISA has instructions for TLB manipulation
 - OS gets to pick the page table format

2/8/2004

© 2004 Ed Lazowska & Hank Levy

16

Managing TLBs (2)

- OS must ensure TLB and page tables are consistent
 - when OS changes protection bits in a PTE, it needs to invalidate the PTE if it is in the TLB
- What happens on a process context switch?
 - remember, each process typically has its own page tables
 - need to invalidate all the entries in TLB! (**flush TLB**)
 - **this is a big part of why process context switches are costly**
 - can you think of a hardware fix to this?
- When the TLB misses, and a new PTE is loaded, a cached PTE must be evicted
 - choosing a victim PTE is called the "TLB replacement policy"
 - implemented in hardware, usually simple (e.g., LRU)

17

Cool Virtual Memory Tricks

- Exploit level of indirection between VA and PA
 - shared memory
 - regions of two separate processes' address spaces map to the same physical frames
 - read/write: access to share data
 - execute: shared libraries!
 - will have separate PTEs per process, so can give different processes different access privileges
 - must the shared region map to the same VA in each process?
 - copy-on-write (COW), e.g., on fork()
 - instead of copying all pages, created shared mappings of parent pages in child address space
 - make shared mappings read-only in child space
 - when child does a write, a protection fault occurs, OS takes over and can then copy the page and resume client

18

- Memory-mapped files

- instead of using open, read, write, close
 - "map" a file into a region of the virtual address space
 - e.g., into region with base 'X'
 - accessing virtual address 'X+N' refers to offset 'N' in file
 - initially, all pages in mapped region marked as invalid
- OS reads a page from file whenever invalid page accessed
- OS writes a page to file when evicted from physical memory
 - only necessary if page is dirty
