CSE 451: Operating Systems
Winter 2023

Module 16
File Systems

Gary Kimura

High Level View

Application Program

I/O (programming interface)

I/O (File Systems)
block I/O
LBN

I/O (device interface)

HW Devices

Slow – Fast
Read/Write – Read only – Write only
Byte or block I/O
Polling – Interrupt
DMA

HDD
SSD

Main Points

- Programming Interface
  - Naming. What the typical programmer sees are Files and Directories
  - Basic operations
- On-disk Structure
  - First general design issues and then a look at Microsoft's FAT file system, Unix, and NTFS.
- Journaling and Recovery

File System mission

- The concept of a file system is simple
  - the implementation of the abstraction for secondary storage
    - abstraction = files
  - logical organization of files into directories
    - the directory hierarchy
  - sharing of data between processes, people and machines
    - access control, consistency, …
- The discussion on file systems often center around two concepts
  - There is the on-disk structure (i.e., how is the data persistently stored on secondary storage)
  - There is the software component that manages the storage and communicates with the user to store and retrieve data (hopefully without any loss of information)

Files

- A file is a collection of data with some properties
  - contents, size, owner, last read/write time, protection …
- Files may also have types
  - understood by file system
    - device, directory, symbolic link
  - understood by other parts of OS or by runtime libraries
    - executable, dll, source code, object code, text file, …
- Type can be encoded in the file's name or contents
  - Windows encodes type in name (and contents)
    - .com, .exe, .bat, .dll, .jpg, .mov, .mp3, …
  - Old Mac OS stored the name of the creating program along with the file
  - Unix does both as well
    - in content via magic numbers or initial characters (e.g., #!)

Programming Interface

- The usual APIs plus maybe a few surprises
  - Open, close, read, write, …
- Files and Directories, the object we play with
- Finding and Enumerating entries in a directory
- Watching for changes
- How do we delete a file?
- Renaming or moving files
- Sequential access versus random access. Who remembers the last access point?
- Shared opens and files locks

Basic operations

Unix

- create(name)
- open(name, mode)
- read(fd, buf, len)
- write(fd, buf, len)
- sync(fd)
- seek(fd, pos)
- close(fd)
- unlink(name)
- rename(old, new)

Windows

- CreateFile(name, CREATE)
- CreateFile(name, OPEN)
- ReadFile(handle, …)
- WriteFile(handle, …)
- FlushFileBuffers(handle, …)
- SetFilePointer(handle, …)
- CloseHandle(handle, …)
- DeleteFile(name)
- CopyFile(name)
- MoveFile(name)

File access methods

- Some file systems provide different access methods that specify ways the application will access data
  - sequential access
    - read bytes one at a time, in order
  - direct access
    - random access given a block/byte #
  - record access
    - file is array of fixed- or variable-sized records
  - indexed access
    - FS contains an index to a particular field of each record in a file
    - apps can find a file based on value in that record (similar to DB)
- Why do we care about distinguishing sequential from direct access?
  - what might the FS do differently in these cases?

Directories

- Directories provide:
  - a way for users to organize their files
  - a convenient file name space for both users and FS's
- Most file systems support multi-level directories
  - naming hierarchies (c:\, c:\DocumentsAndSettings, c:\DocumentsAndSettings\User, …)
- Most file systems support the notion of current directory
  - absolute names: fully-qualified starting from root of FS
    - `C:\> cd c:\Windows\System32`
  - relative names: specified with respect to current directory
    - `C:\> c:\Windows\System32` (absolute)
    - `C:\Windows\System32> cd Drivers`
    - (relative, equivalent to cd **`c:\Windows\System32\Drivers`**)

Directory internals

- A directory is typically just a file that happens to contain special metadata
  - directory = list of (name of file, file attributes)
  - attributes include such things as:
    - size, protection, location on disk, creation time, access time, …
  - the directory list can be unordered (effectively random)
    - when you type “ls” or “dir /on” , the command sorts the results for you.
    - some file systems organize the directory file as a BTree, giving a “natural” ordering
      - What case to use for sort?
      - What about international issues?

Back to some of the more unexpected functions

- Finding and Enumerating entries in a directory
- Watching for changes
- How do we delete a file?
- Renaming or moving files. What if someone else has the file open?
- Shared opens and files locks
- Tunnelling, version control and files attributes

A deeper look into File Systems

- Design Constraints and options
- On-Disk structure

File System Design Constraints

- For small files:
  - Small blocks for storage efficiency
  - Files used together should be stored together
- For large files:
  - Contiguous allocation for sequential access
  - Efficient lookup for random access
- May not know at file creation
  - Whether file will become small or large

File System Design

- Data structures
  - Directories: file name -> file metadata
    - Store directories as files
  - File metadata: how to find file data blocks
  - Free map: list of free disk blocks
- How do we organize these data structures?
  - Device has non-uniform performance

Design Challenges

- Index structure
  - How do we locate the blocks of a file?
- Index granularity
  - What block size do we use?
- Free space
  - How do we find unused blocks on disk?
- Locality
  - How do we preserve spatial locality?
- Reliability
  - What if machine crashes in middle of a file system op?

File System Design Options

	FAT	FFS	NTFS
Index structure	Linked list	Tree (fixed, assym)	Tree (dynamic)
granularity	block*	block*	extent
free space allocation	FAT array	Bitmap (fixed location)	Bitmap (file)
Locality	defragmentation	Block groups + reserve space	Extents Best fit defrag

* Really a collection of one or more of logical blocks, commonly referred to as a cluster.

Microsoft's File Allocation Table (FAT)

- Introduced in DOS in the early 1980's
- Linked list index structure
  - Simple, easy to implement
  - Still widely used (e.g., thumb drives)
- File table:
  - Linear map of all blocks on disk
  - Each file a linked list of blocks
- Allocation granularity (cluster size)

FAT disk layout

- Reserved Area (Boot sector and FAT)
- Root Directory Area
- Data Region

Dirents: contain: Filename, Attributes, Times (creation, last access, write), First cluster of file, Filesize, and a few more things

FAT

- Evolution:
  - Floppy disk and 12-bit FAT
  - Hard drives and 16-bit FAT with subdirectories
  - Larger drives and 32-bit FAT
- Pros:
  - Easy to find free block
  - Easy to append to a file
  - Easy to delete a file
- Cons:
  - Small file access is slow
  - Random access is very slow
  - Fragmentation
    - File blocks for a given file may be scattered
    - Files in the same directory may be scattered
    - Problem becomes worse as disk is used

The original Unix file system

- Dennis Ritchie and Ken Thompson, Bell Labs, 1969
- "UNIX rose from the ashes of a multi-organizational effort in the early 1960s to develop a dependable timesharing operating system" – Multics
- Designed for a "workgroup" sharing a single system
- Did its job exceedingly well
  - Although it has been stretched in many directions and made ugly in the process
- A wonderful study in engineering tradeoffs

All disks are divided into five parts …

- Boot block
  - can boot the system by loading from this block
- Superblock
  - specifies boundaries of next 3 areas, and contains head of freelists of inodes and file blocks
- i-node area
  - contains descriptors (i-nodes) for each file on the disk; all i-nodes are the same size; head of freelist is in the superblock
- File contents area
  - fixed-size blocks; head of freelist is in the superblock
- Swap area
  - holds processes that have been swapped out of memory

So …

- You can attach a disk to a dead system …
- Boot it up …
- Find, create, and modify files …
  - because the superblock is at a fixed place, and it tells you where the i-node area and file contents area are
  - superblock also contains i-node number of root directory

The flat (i-node) file system

- Each file is known by a number, which is the number of the i-node
  - seriously – 0, 1, 2, 3, etc.!
  - why is it called “flat”?
- Files are created empty, and grow when extended through writes

The tree (directory, hierarchical) file system

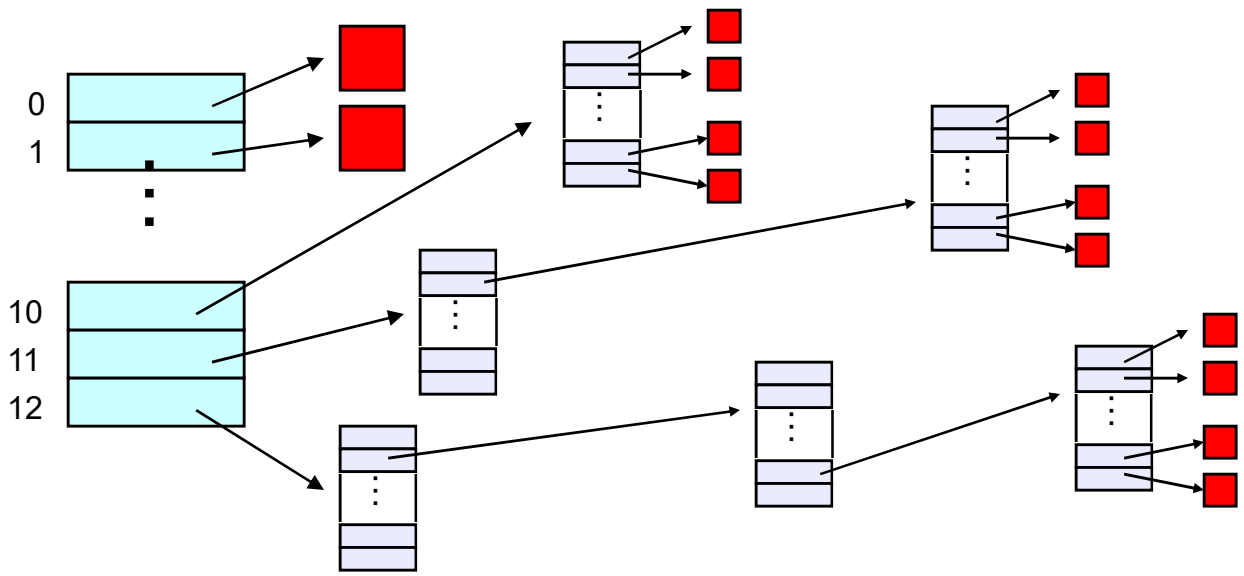
- A directory is a flat file of fixed-size entries
- Each entry consists of an i-node number and a file name

i-node number	File name
152	.
18	..
216	my_file
4	another_file
93	oh_my_god
144	a_directory

- It's as simple as that!

The "block list" portion of the i-node (Unix Version 7)

- Points to blocks in the file contents area
- Must be able to represent very small and very large files. How?
- Each inode contains 13 block pointers
  - first 10 are "direct pointers" (pointers to 512B blocks of file data)
  - then, single, double, and triple indirect pointers



Protection

- Objects: individual files
- Principals: owner/groups/everyone
- Actions: read/write/execute

- This is pretty simple and rigid, but it has proven to be about what we can handle!

File system consistency

- Both i-nodes and file blocks are cached in memory
- The “sync” command forces memory-resident disk information to be written to disk
  - system does a sync every few seconds
- A crash or power failure between sync’s can leave an inconsistent disk
- You could reduce the frequency of problems by reducing caching or via write-through, but performance would suffer big-time

Consistency of the Flat file system

- Is each block accounted for?
  - Belongs to precisely one file or is on free list
  - What to do if in multiple files?
- Mark-and-sweep garbage collection of disk space
  - Start with bitmap (one bit per block) of zeros
  - For every inode, walk allocation tree setting bits
  - Walk free list setting bits
  - Bits that are one along the way?
  - Bits that are zero at the end?

Consistency of the directory structure

- Verify that directories form a tree
- Start with vector of counters, one per inode, set to zero
- Perform tree walk of directories, adjusting counters on every name reference
- At end, counters must equal link count
  - What do you do when they don't?

Journaling File Systems

- Became popular ~2002, but date to early 80's
- There are several options that differ in their details
  - Ntfs (Windows), Ext3 (Linux), ReiserFS (Linux), XFS (Irix), JFS (Solaris)
- Basic idea
  - update metadata, or all data, *transactionally*
    - *"all or nothing"*
    - *Failure atomicity*
  - if a crash occurs, you may lose a bit of work, but the disk will be in a consistent state
    - more precisely, you will be able to quickly get it to a consistent state by using the transaction log/journal – rather than scanning every disk block and checking sanity conditions

Why are journaling file systems so popular?

- In any file system buffering is necessary for performance
- But suppose a crash occurs during a file creation:
    - Allocate a free inode
    - Point directory entry at the new inode
- In general, after a crash the disk data structures may be in an inconsistent state
    - metadata updated but data not
    - data updated but metadata not
    - either or both partially updated
- fsck (i-check, d-check) are *very* slow
    - must touch every block
    - worse as disks get larger!

Where is the Data?

- In the file systems we have seen already, the data is in two places:
  - On disk
  - In in-memory caches
- The caches are crucial to performance, but also the source of the potential "corruption on crash" problem
- The basic idea of the solution:
  - Always leave "home copy" of data in a consistent state
  - Make updates persistent by writing them to a sequential (chronological) journal partition/file
  - At your leisure, push the updates (in order) to the home copies and reclaim the journal space
  - Or, make sure log is written before updates

• Undo/Redo log

- Log: an append-only file containing log records
  - <start t>
    - transaction t has begun
  - <t,x,v>
    - transaction t has updated block x and its new value is v
      - Can log block "diffs" instead of full blocks
      - Can log *operations* instead of data (operations must be idempotent and undoable)
  - <commit t>
    - transaction t has committed – updates will survive a crash
- Committing involves writing the records – the home data needn't be updated at this time

If a crash occurs

- Open the log and parse
  - <start> <commit> => committed transactions
  - <start> no <commit> => uncommitted transactions
- Redo committed transactions
  - Re-execute updates from all committed transactions
  - Aside: note that update (write) is *idempotent*: can be done any positive number of times with the same result.
- Undo uncommitted transactions
  - Undo updates from all uncommitted transactions
  - Write “compensating log records” to avoid work in case we crash during the undo phase

Managing the Log Space

- A cleaner thread walks the log in order, updating the home locations (on disk, not the cache!) of updates in each transaction
  - Note that idempotence is important here – may crash while cleaning is going on
- Once a transaction has been reflected to the home blocks, it can be deleted from the log

Impact on performance

- The log is a big contiguous write
  - very efficient, but it IS another I/O
- And you do fewer scattered synchronous writes
  - very costly in terms of performance
- So journaling file systems can actually improve performance (but not in a busy system!)
- As well as making recovery very efficient

NTFS

- Developed for Windows NT in the early 1990's
- Master File Table
  - Flexible 1KB storage for metadata and data
- Extents
  - Block pointers cover runs of blocks
  - Similar approach in linux (ext4)
  - File create can provide hint as to size of file
- Journalling for reliability
- A basic underlying design principle: Everything on the disk is represented as a file and accessible through the usual file operations (read, write, etc.)

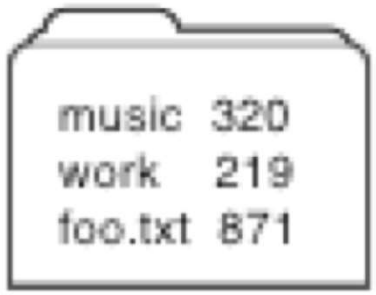
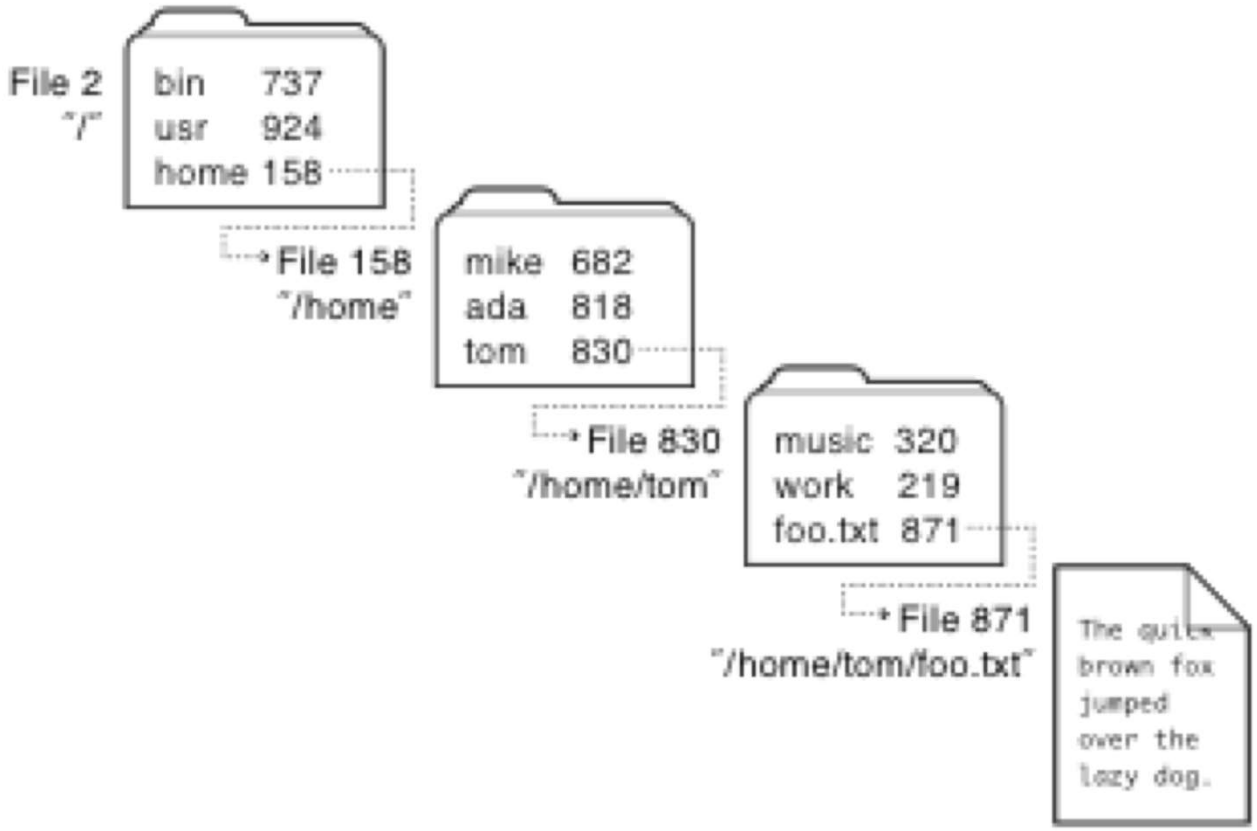
Directories Are Files



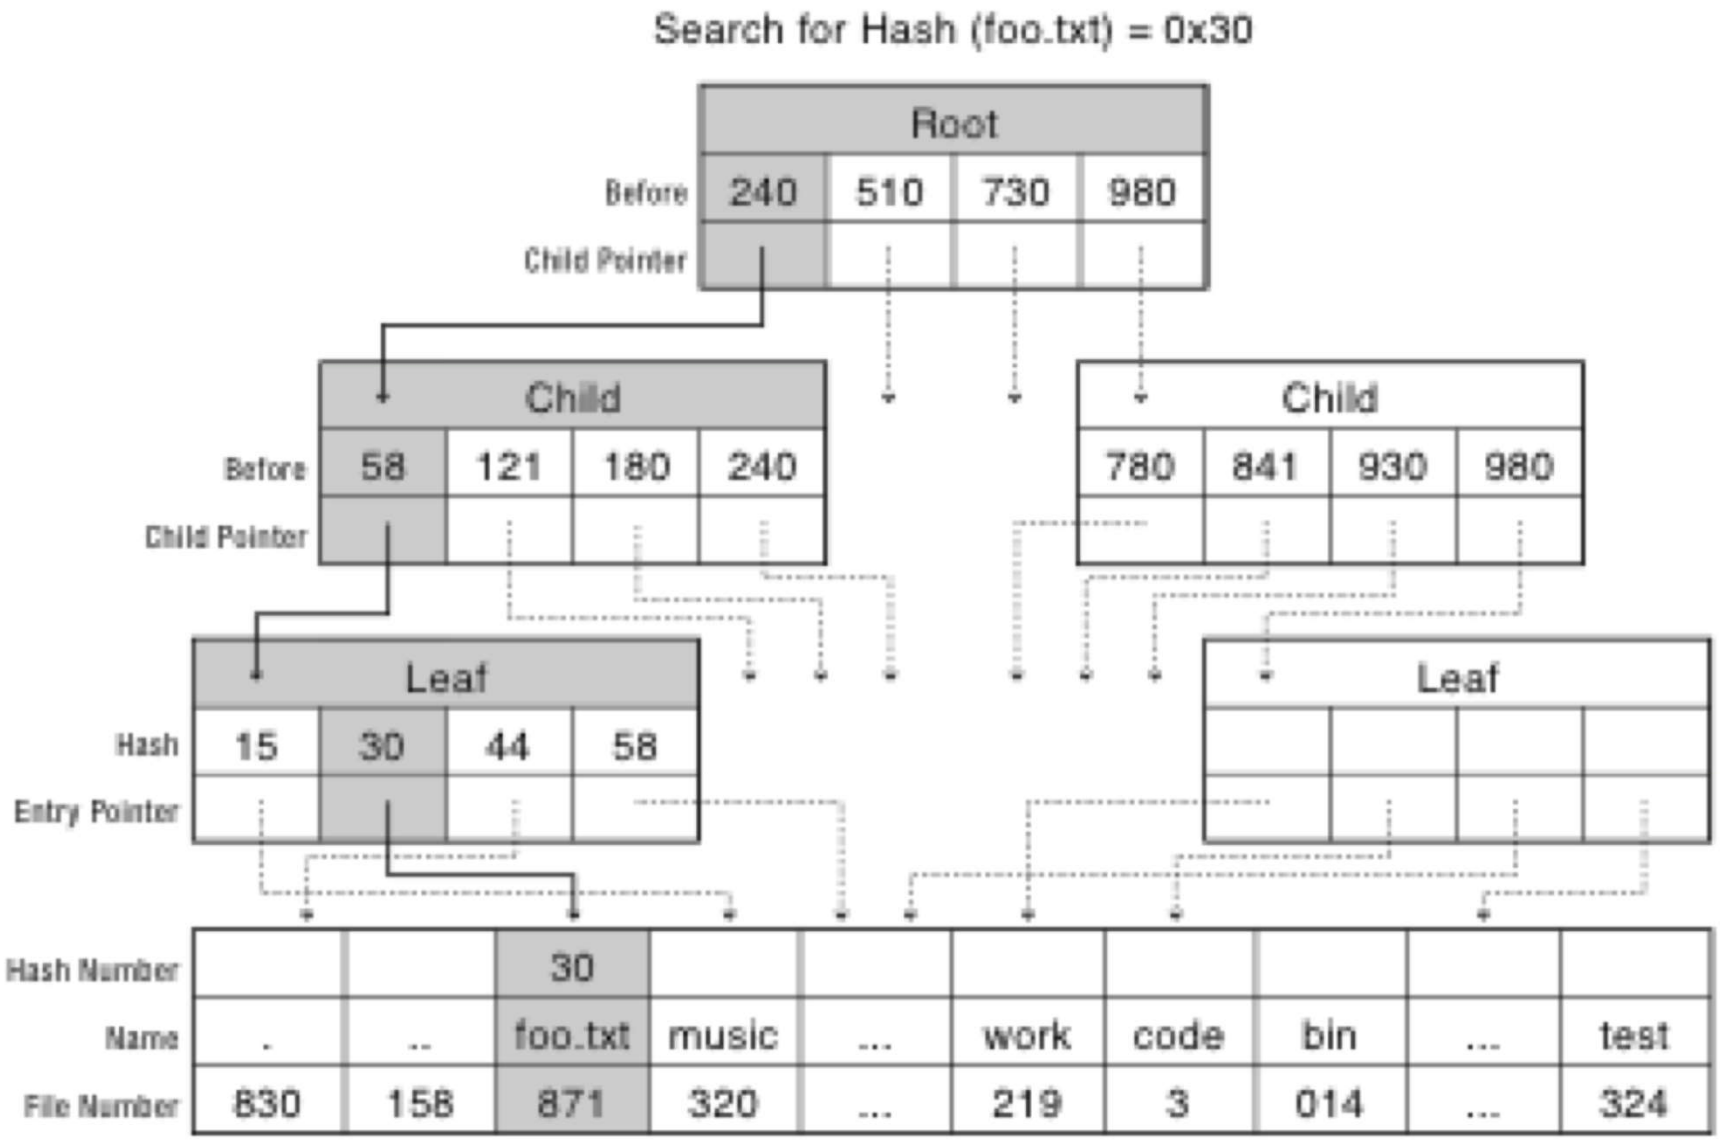
Recursive Filename Lookup



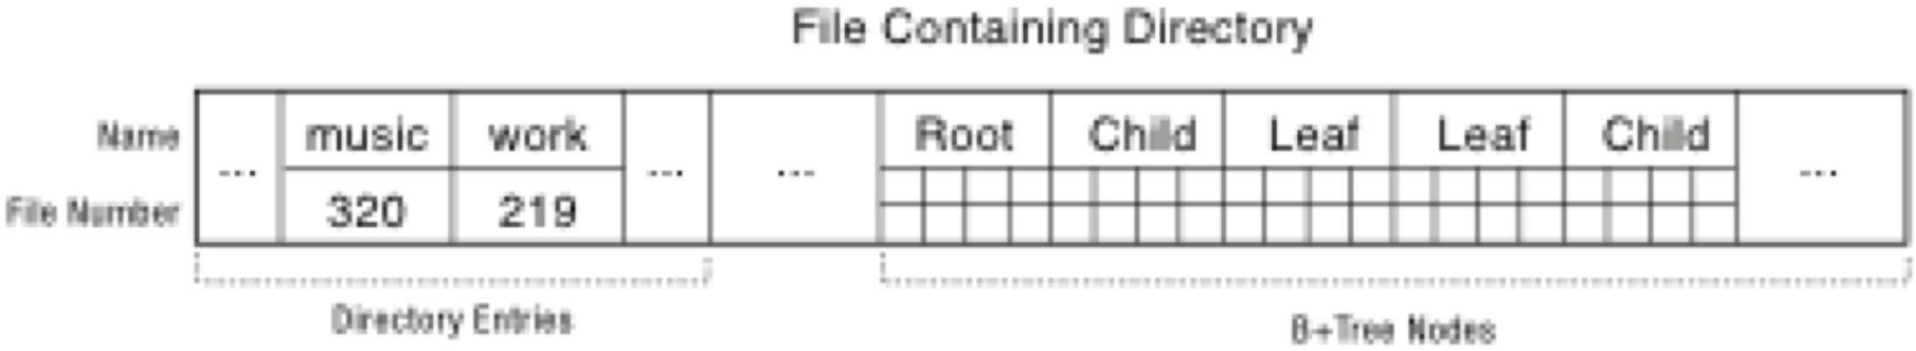
Directory Layout

- Directory stored as a file
- Linear search to find filename (small directories)

Large Directories: B Trees



Large Directories: Layout



NTFS Features

- Journaling (logging) for quick recovery
- Individual lossless file compression and sparse files
- Symbolic links and hard links
- Unicode Filenames with accompanying collation table
- Random and sequential access
- Able to extend (i.e., add disks) to a volume.
- Fragmentation
- An obscure feature (?) to handle legacy apps that used short 8.3 (Eight Dot Three) names.
- Access Control Lists
- Alternate Data Streams
