CRYPTOCURRENCY

Ellis Michael h/t Tom Anderson

DECENTRALIZED CONTROL

 PBFT and similar protocols require public-key servers are.

- protocol to run.
- Otherwise, these protocols are susceptible to **Sybil** attacks.
- What if you want a decentralized system?

infrastructure and that the servers know who the other

• This must be setup by some central authority for the

TWO CLASSES OF SOLUTIONS

PROOF OF WORK

- Rate of transaction commitment is limited by cryptographically hard problem.
- Nodes called miners solve these problems to commit transactions.
- Assumes that a majority of the CPU power is controlled by honest* nodes.
- Miners are rewarded with transaction fees and mining rewards.

PROOF OF STAKE

- Transactions are committed with votes weighted by the amount of stake voters have in the system.
- Assumes that a 2/3rds of the money is controlled by honest* nodes.
- Voters sometimes rewarded for taking part in the protocol. (But they also have stake in the system.)

BITCOIN

- Bitcoin is a proof-of-work cryptocurrency network, started in 2009.
- Goal: electronic money without the need for trust.
- Relies on cryptography for authentication, proof-ofwork for transaction ordering.

BITCOIN TRANSACTIONS

- Payment is a signed, publicly visible transaction between public/private key pairs.
- Transactions have (potentially multiple) inputs and outputs.
- Transaction inputs are other transactions.
 - Transaction outputs are public keys (recipients).

"Lukas takes the 42 bitcoins he got from transaction abc123 and the 8 BTC from transaction def456 and pays Arvind's public key 45 BTC. Lukas pays himself the remaining 5 BTC."

[signed with Lukas's private key]

Transaction

STRAWMAN PROPOSAL

- What could go wrong?
 - doesn't have Lukas's private key.
 - question? This is called double-spending.
 - Where does money actually come from?

Lukas just signs the transaction and gives it to Arvind.

- Arvind couldn't have impersonated Lukas. He

- What if the sender already spent the transaction in

TRUSTED THIRD PARTIES (NOT A STRAWMAN)

- party (or system).
- As long as the transaction is valid (i.e., the input transactions weren't already spent), accepts the listeners).

• The sender could send the transaction to a trusted third

transaction and puts it in a log. The log is made publicly visible (and can be replicated by any number of passive

The recipients of a transaction wait until they see the transaction in the log. Once it's there, it's been committed.

MANAGING THE PUBLIC LOG

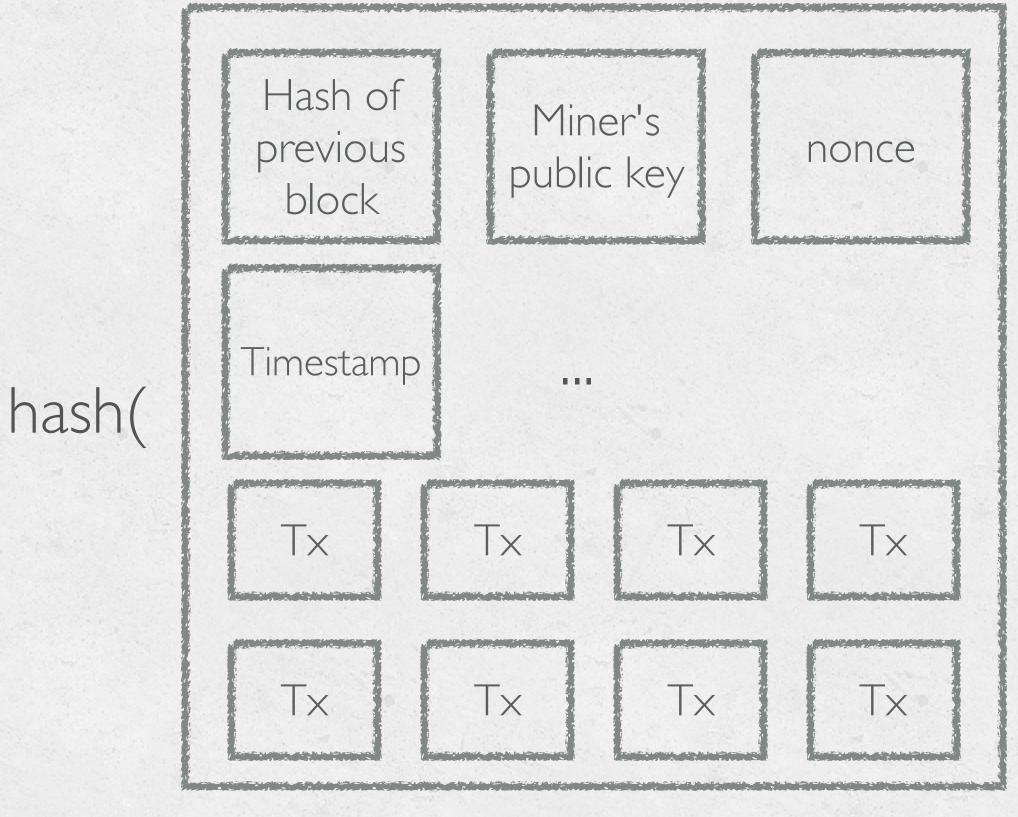

• We need the log to stay consistent (i.e., that transactions stay in the same order in the log).

• We could use Paxos, but what if the replicas aren't trusted?

• PBFT still requires trusting 2f+1 replicas.

BITCOIN MINING

- Bitcoin commits transactions by having servers called **miners** solve a cryptographic puzzle.
- Transactions are committed in blocks.
- Miners try to find a nonce such that the hash of the entire block is less than some threshold.
- Finding such a nonce is difficult. But miner's get compensated in the form of mining rewards (bitcoin from nowhere) and transaction fees (bitcoin from the transaction senders).

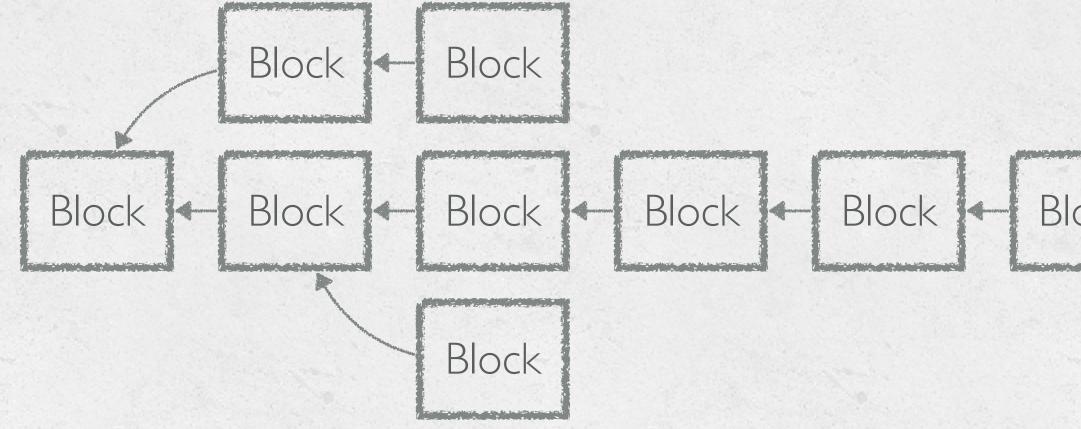

Block

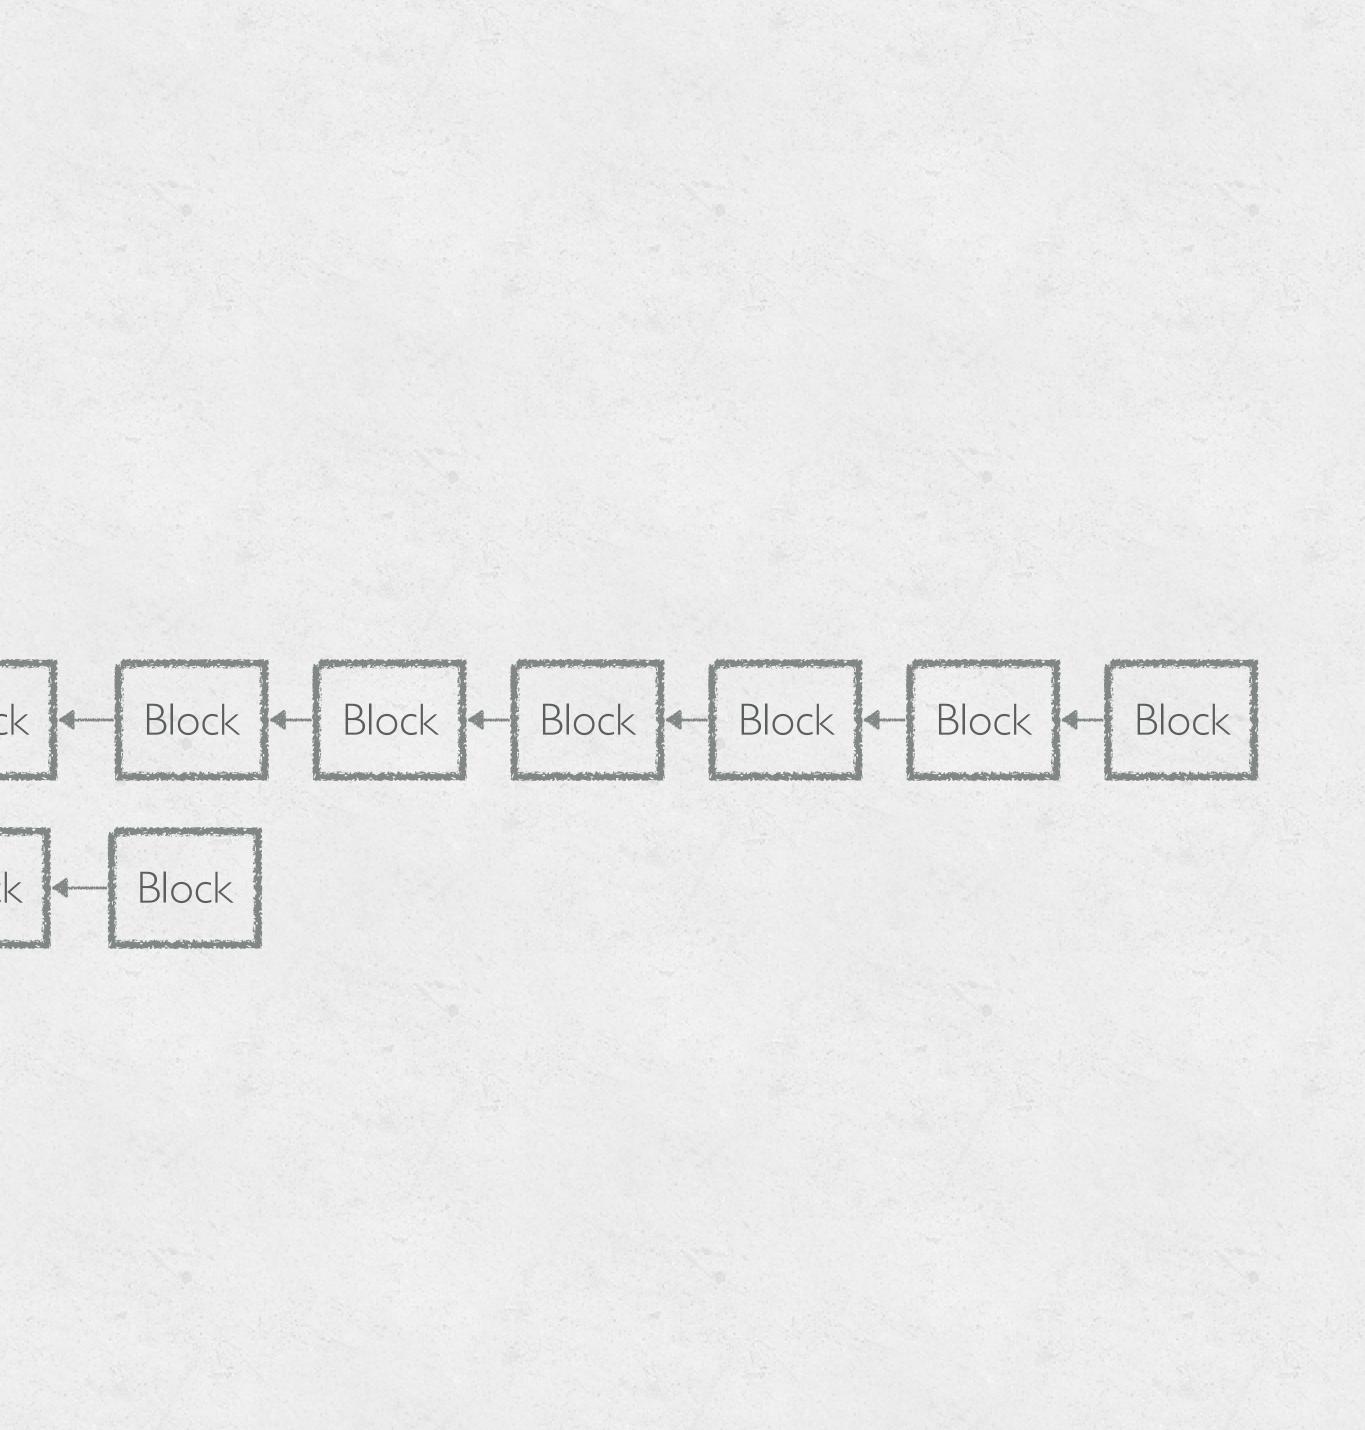

FINDING A STABLE ORDER

- Each block has a single pointer to the previous block (except for the initial block). These blocks then form a DAG.
- Honest miners work off of the **longest chain**. If they see two chains of equal length, they work off the one they saw first. (What about greedy miners?)
- Only transactions with unspent inputs are valid.
- Normally, clients wait for transactions to be 6 blocks deep (i.e., that it's in a chain 6 blocks longer than any chain without the transaction) before considering it confirmed.
- As long as honest miners control >50% of the hashing power, the longest chain can't be overrun. Confirmed transactions won't be undone by a double-spend.

NETWORK PROTOCOL

new blocks and transaction requests.

• Peer list is bootstrapped usually using DNS by asking for a hostname that points to known nodes.

Bitcoin uses a gossip protocol to communicate

• Each peer is connected to a set of other peers.

HASH PUZZLE DIFFICULTY

- The threshold for the mining puzzle is by the difficulty, a 256 bit number.
- given nonce. 2²⁵³ gives a 1/4 chance, etc.

• If the difficulty is 2²⁵⁴, there's a 1/2 chance for any

• The difficulty is adjusted every 2016 blocks to keep the average throughput at ~1 block/10 mins.

• The average time to confirm a transaction is 1 hour.

MINING REWARDS

- This reward started at 50 BTC and is halved every 210,000 blocks (approximately every 4 years).
- maximum of 21M BTC.

• Every time a block is "mined," the miner gets a reward.

 Since bitcoins aren't infinitely divisible, the reward will go to 0 at some point. There will only every be a

Currently, about 85% of all bitcoins have been mined.

TRANSACTION FEES

- winning miner.
- commit that transaction.
- incentive.
- BTC (=\$4 at current prices).

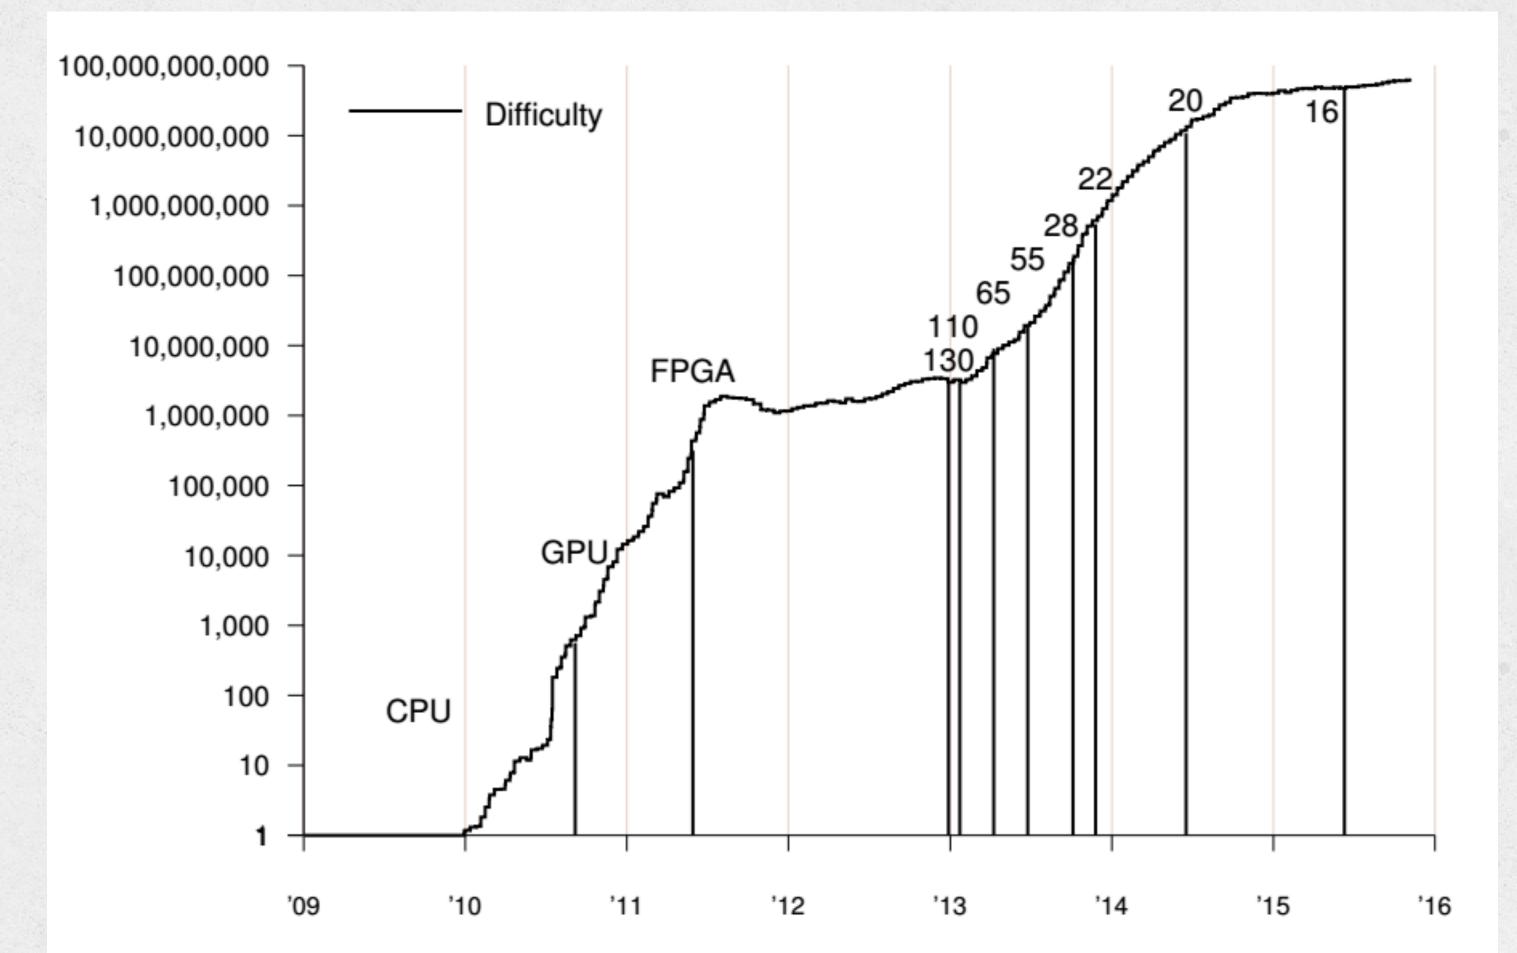

Transaction senders also pay a fee that is claimed by the

• The higher the fee, the more incentivized miners are to

• Once all bitcoins are mined, this will be the only mining

Currently, transaction fees are averaging about 0.00050

BITCOIN HARDWARE PROGRESSION

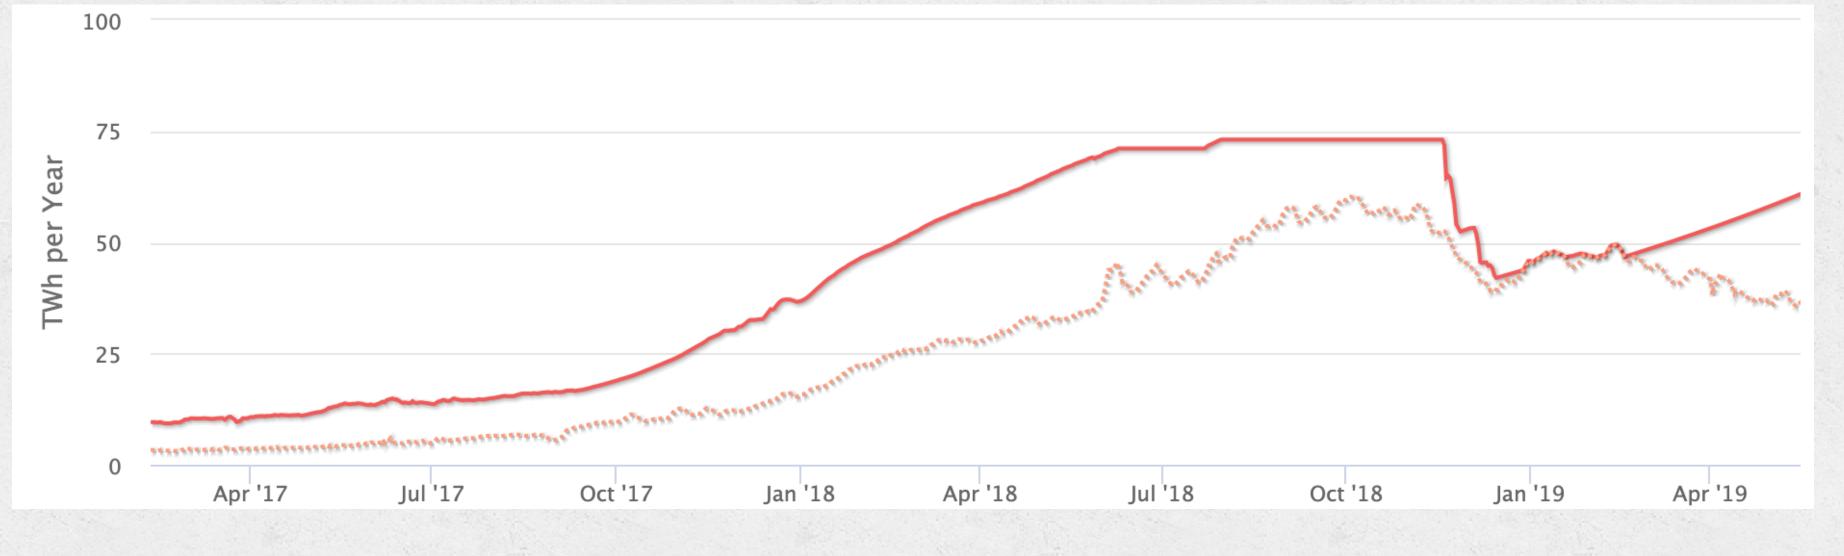

HASHING - LIKE MACHINE LEARNING BUT LESS USEFUL

- Currently, the overall hashrate is 55 EH (exahash)/s.
- same amount of energy as Switzerland (!).

• Even with specialized hardware, hashing is energy-intensive.

• The entirety of the bitcoin mining network consumes the

BITCOIN THROUGHPUT

• Currently, there are an average of 2,500 transactions in a 2MB bitcoin block.

 The network mines a block once every 10 minutes on average.

This gives us ~4 transactions/s.

WHAT DID THIS GET US?

- Privacy?
 - transaction to another is public.
- Non-repudiation?
 - Why couldn't a bank guarantee this?
- No trusted authority?
- No centralized monetary policy?
 - You **like** deflation?

- Well, not really. Your name isn't published, but the flow of money from one

- Great, now drug dealers and human traffickers get financial infrastructure, too!

JAN 2013	JAN 2014	FEB 2015	
Market cap		Volume (24 hours)	
\$139.2B		\$24.9B	

Does this look like a currency?

Why are people putting their money in this?

OTHER PROOF-OF-WORK SYSTEMS

based system.

- even better for money laundering?)
- Etherium allows scripting.
- **Ripple** tries to maintain a stable price.
- ...and many others...

Bitcoin is by no means the only popular proof-of-work

• **Zerocoin** provides better anonymity (which makes it

BITCOIN DISCUSSION QUESTIONS

- Where does value of a Bitcoin come from?
- Is the energy consumption of Bitcoin worth it?
- How valuable is decentralization, really?
- Is Bitcoin useful as a currency? For small transactions?
- How long will SHA-256 last?
- How do we make changes to the protocol?
- Is Bitcoin actually anonymous?

- Is Bitcoin ethical given its benefits for ransomware, money laundering, etc.? • Why do wallets and private exchanges exist? Don't they defeat the purpose? • What if miners are rational (greedy) instead of honest? What implications does the non-reversibility of Bitcoin have?

PROOF-OF-STAKE

Algorand

- Created in 2017.
- Uses proof-of-stake instead of proof-of-work (but not the first).
- Apparently now one of approx. 300 billion blockchain startups.

Algorand

BORDERLESS ECONOMY. BOUNDLESS OPPORTUNITY.

Algorand is defining the standard for blockchain technology.

Our pure proof-of-stake protocol is the first of its kind to support the scale, open participation, and transaction finality for billions of users. All backed by a sustainable business and a renowned team of experts.

LEARN MORE

MAIN DEAS

- Weight users by how much money they hold in their account.
- Use Byzantine agreement, but rather than doing Byzantine
- target committee members ahead of time.
- Each committee is only used for a **single step**. As soon as a and can't be targeted.

agreement over all users, use a randomly selected committee.

• Choose the committees based on cryptographic sortion. Uses a verifiable random functions on publicly available data and secret information held by the participants so that the adversary can't

committee member reveals their decision, they're no longer relevant

GOAL

- need to agree on an ordering of the transactions (blocks).
- honest users running bug-free code.
- The system should be reasonably performant and scalable.

• The transaction structure is the same as Bitcoin. We just

• We want safety (linearizability) with high probability.

• We assume that at least 2/3 of the money is held by

VERIFIABLE RANDOM FUNCTIONS

A VRF is like a modified hash function.

$VRF(x, sk) = h, \pi$

- x is an input string
- sk is a secret key
- h is a hash
- verify the results (doesn't reveal secret key).

 π is a proof that anyone knowing the public key can use to

CRYPTOGRAPHIC SORTION

Bottom line: the output of the VRF determines whether (and how many times) a user is chosen for a particular role.

- **τ**: number of expected users for a given role.
- **w**: amount of currency that user controls.
- W: amount of total currency.
- seed: each round's seed proposed along with block using VRF of previous seeds.

procedure Sortition(sk, seed, τ , role, w, W): $\langle hash, \pi \rangle \leftarrow VRF_{sk}(seed || role)$ $p \leftarrow \frac{\tau}{W}$ $j \leftarrow 0$ **while** $\frac{hash}{2^{hashlen}} \notin \left[\sum_{k=0}^{j} B(k; w, p), \sum_{k=0}^{j+1} B(k; w, p) \right) \mathbf{do}$ $\downarrow j_{++}$ **return** $\langle hash, \pi, j \rangle$ **Algorithm 1:** The cryptographic sortition algorithm.

Algorithm 2: Pseudocode for verifying sortition of a user with public key *pk*.

ROUND STRUCTURE

- Each round is an opportunity to commit some block.
- First, proposers are chosen and propose blocks.
- choose a block from among the proposed ones.
- BA* proceeds in two phases. First, it reduces the problem to between those.

• Next, the system runs BA*, their main agreement protocol, to

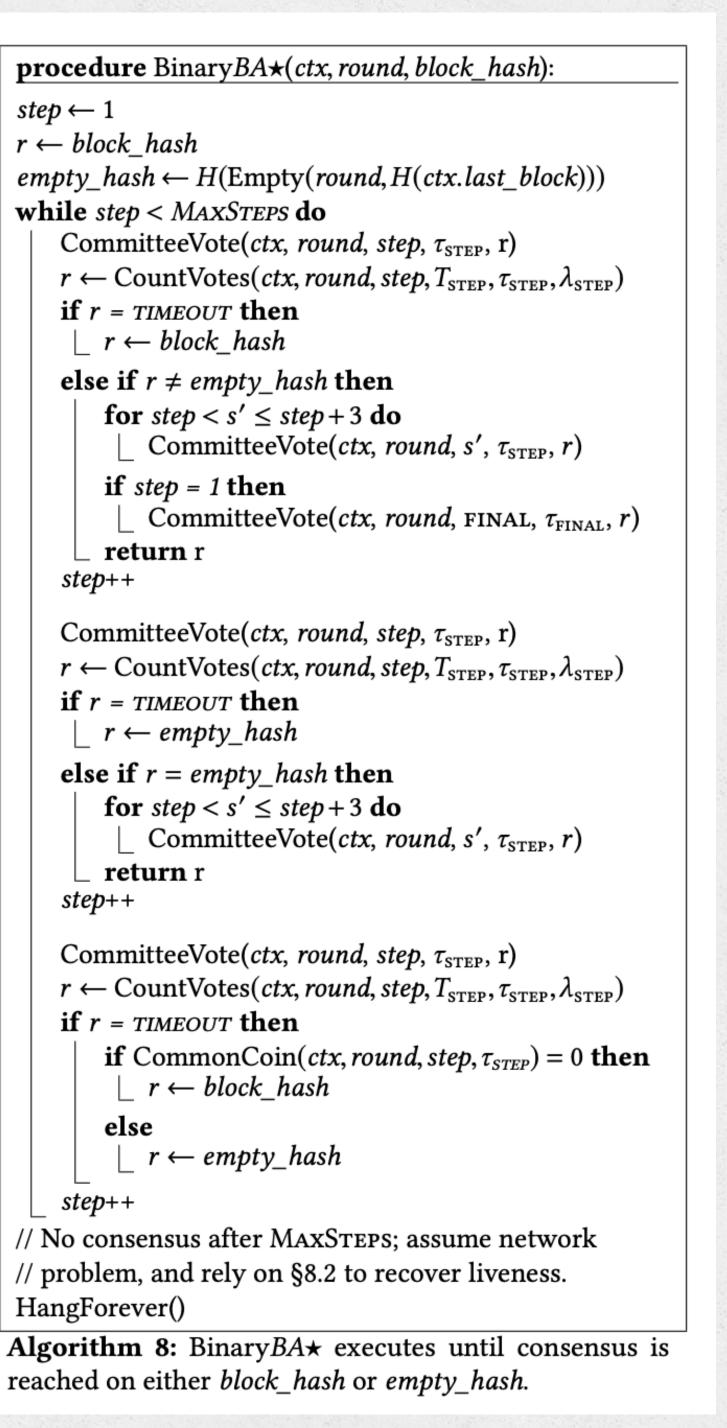

choosing between two options. Then, it runs BinaryBA* to choose

 BA* can either reach TENTATIVE or FINAL agreement. A block is committed if it is FINAL or if one of the block's successors is FINAL.

BINARYBA*

- Essentially, a modified version of the **Ben-Or randomized consensus** algorithm.
- It uses a shared random coin to reach consensus faster.
- Random coin is biased using the hashes of messages from the previous step. Even if the adversary controls the network, it can't delay consensus forever (since it can't influence the hash values).
- With strong synchrony, BinaryBA* finishes quickly with high probability.

procedure CommonCoin(*ctx*, *round*, *step*, τ): $minhash \leftarrow 2^{hashlen}$ **for** $m \in incomingMsgs[round, step]$ **do** $\langle votes, value, sorthash \rangle \leftarrow \operatorname{ProcessMsg}(ctx, \tau, m)$ for $1 \le j < votes$ do $h \leftarrow H(sorthash||j)$ **if** h < minhash **then** $minhash \leftarrow h$; return minhash mod 2 Algorithm 9: Computing a coin common to all users.

reached on either *block_hash* or *empty_hash*.

ALGORAND TAKEAWAYS

- Algorand doesn't utilize proof-of-work and instead weights users based on how much money they have in the system.
- Algorand is more communication efficient since it is committee based.
- However, it is not clear what incentives users have to participate in the protocol (their stake in the system notwithstanding).
- Algorand requires money holders to be online and broadcasting their address to the world.
- Algorand is really complicated.
