Channel coding aka Forward Error Correction

- "My communication system is working, but I am getting a lot of errors...what can I do?"
- CRC is an error DETECTING code...it spots errors with high probability, but doesn't tell you how to fix them
- Error CORRECTING codes can actually allow you to repair the errors...if there aren't too many

- Channel coding is adding redundancy to improve reliability, at a cost in rate
 - Error correction
- Source coding is removal of redundancy from information bits to improve rate
 - Compression
- This lecture is only about channel coding

How do error correcting codes work?

- Basic idea: add redundancy (extra bits) to make communication more robust
 - Or, put another way, don't allow all bit patterns, just a subset...if you receive an invalid bit sequence, correct to the closest valid bit sequence
- The extra bits (or disallowed bit patterns) reduce the net communication rate:
 - If "information bits" are denoted i and "error correction bits" denoted ec, then the new rate, with error correction is i/(i+ec)
 - □ The original rate, with no error correction (ec=0) is 1.0

Noisy communication channels

A model for the noise in the channel

Binary Symmetric Channel (BSC) with f=0.1
 f: probability of bit *f*lip

$$x \stackrel{0}{\longrightarrow} \stackrel{0}{\longrightarrow} \stackrel{0}{1} y \stackrel{P(y=0 \mid x=0)}{=} = 1 - f; \quad P(y=0 \mid x=1) = f; \\ P(y=1 \mid x=0) = f; \qquad P(y=1 \mid x=1) = 1 - f.$$

Other important channels: *Erasure Channel* (models packet loss in wired or wireless networks)

Example 1: Repetition code, "R3"

Received codeword	Decoded as
000	0 (no errors)
001	0
010	0
100	0
111	1 (no errors)
110	1
101	1
011	1

- Each 1 information bit gets encoded to 3 transmitted bits, so the rate of this code is 1/3
- If you think of the first bit as the message, and bits 2 and 3 as the error correction bits, then the rate also turns out to be 1/(1+2) = 1/3
- This code can correct 1 bit flip, or 2 bit erasures (erasures not shown)

Problems with R3

Figure 1.11. Transmitting 10 000 source bits over a binary symmetric channel with f = 10%using a repetition code and the majority vote decoding algorithm. The probability of decoded bit error has fallen to about 3%; the rate has fallen to 1/3.

Noise set to flip 10% of the bits

Rate is only 1/3 Still 3% errors remaining after error correction...Crummy!

Example 2: Random code

Original message	Codewords transmitted
000	10100110
001	11010001
010	01101011
011	00011101
100	01101000
101	11001010
110	10111010
111	00010111

Each block of 3 info bits mapped to a random 8 bit vector...rate 3/8 code. Could pick any rate, since we just pick the length of the random code words. Note that we are encoding blocks of bits (length 3) jointly Problems with this scheme:

(1) the need to distribute and store a large codebook

(2) decoding requires comparing received bit vectors to entire codebook

An error correcting code selects a subset of the space to use as valid messages (codewords). Since the number of valid messages is smaller than the total number of possible messages, we have given up some communication rate in exchange for robustness. The size of each ball above gives approximately the amount of redundancy. The larger the ball (the more redundancy), the smaller the number of valid messages The name of the game

In ECCs is to find mathematical schemes that allow time- and space-efficient encoding and decoding, while providing high communication rates and low bit error rates, despite the presence of noise

Types of ECC

- Algebraic
 - Hamming Codes
 - Reed-Solomon [CD, DVD, hard disk drives, QR codes]

BCH

- Sparse graph codes
 - Turbo [CDMA2000 1x]
 - Repeat accumulate
 - LDPC (Low Density Parity Check)
 - [WiMax, 802.11n, 10GBase 10 802.3an]
 - Fountain / Tornado / LT / Raptor (for erasure)
 - [3GPP mobile cellular broadcast, DVB-H for IP multicast]

Other ECC terminology

- Block vs. convolutional
- Linear
- Systematic / non-Systematic
 - Systematic means original information bits are transmitted unmodified.
 - Repetition code is systematic
 - Random code is not (though you could make a systematic version of a random code...append random check bits that don't depend on the data...would not be as good as parity bits that do depend on the data)

b--example: 1000→1000101

Rate 4/7 code

Don't encode 1 bit at a time, as in the repetition code Encode blocks of 4 source bits to blocks of 7 transmitted $s_1s_2s_3s_4 \rightarrow t_1t_2t_3t_4t_5t_6t_7$ Where $t_1 - t_4$ are chosen s.t. $s_1s_2s_3s_4 \rightarrow s_1s_2s_3s_4t_5t_6t_7$ Set parity check bits $t_5 - t_7$ using $t_5=s_1+s_2+s_3 \mod 2 \rightarrow 1+0+0 = 1$ $t_6=s_2+s_3+s_4 \mod 2 \rightarrow 0+0+0 = 0$ $t_7=s_1+s_3+s_4 \mod 2 \rightarrow 1+0+0 = 1$ Derity check bits $t_5 - t_7$ using $algorithms \oplus algorithms \oplus algori$

Parity check bits are a linear function information bits...a linear code

The 16 codewords of the (7,4) Hamming code:

s	t	s	t	s	t	s	t
0000	0000000	0100	0100110	1000	1000101	1100	1100011
0001	0001011	0101	0101101	1001	1001110	1101	1101000
0010	0010111	0110	0110001	1010	1010010	1110	1110100
0011	0011100	0111	0111010	1011	1011001	1111	1111111

Any pair of codewords differs in at least 3 bits!

Since it is a linear code, we can write the encoding operation as a matrix multiply (using mod 2 arithmetic):

t=G^Ts where

If received vector r = t+n (transmitted plus noise), then write r in circles:

David MacKay Information Theory, Inference, and Learning Algorithms © Cambridge Univ. Press 2003

Compute parity for each circle (dash→violated parity check)Dashed line→parityPattern of parity checks is called the "syndrome"Dashed line→parityError bit is the unique one inside all the dashed circles* → bit flipped

Each of the 3 circles is either dotted (syndrome=1) or solid (syndrome = 0) → 2³=8 possibilities

Syndrome \mathbf{z}	000	001	010	011	100	101	110	111
Unflip this bit	none	r_7	r_6	r_4	r_5	r_1	r_2	r_3

What happens if there are 2 errors?

*s denote actual errors Circled value is incorrectly inferred single-bit error Optimal decoder actually adds another error in this case...so we started with 2 errors and end with 3

Larger (7,4) Hamming example

Comparing codes

Binary symmetric channel with f = 0.1Error probability p_b vs communication rate R for repetition codes, (7,4) Hamming code, BCH codes up to length 1023

What is the best a code can do?

- How much noise can be tolerated?
- What SNR do we need to communicate reliably?
- At what rate can we communicate with a channel with a given SNR?
 - What error rate should we expect?

What is the best a code can do?

Binary symmetric channel with f =0.1

 $R = C / (1 - H_2(p_b))$ where $H_2 = -p_b \log_2 p_b - (1 - p_b) \log_2(1 - p_b)$

Better codes

b--example: 1000→1000101

Rate 4/7 code

Don't encode 1 bit at a time, as in the repetition code Encode blocks of 4 source bits to blocks of 7 transmitted $s_1s_2s_3s_4 \rightarrow t_1t_2t_3t_4t_5t_6t_7$ Where $t_1 - t_4$ are chosen s.t. $s_1s_2s_3s_4 \rightarrow s_1s_2s_3s_4t_5t_6t_7$ Set parity check bits $t_5 - t_7$ using $t_5=s_1+s_2+s_3 \mod 2 \rightarrow 1+0+0 = 1$ $t_6=s_2+s_3+s_4 \mod 2 \rightarrow 0+0+0 = 0$ $t_7=s_1+s_3+s_4 \mod 2 \rightarrow 1+0+0 = 1$ Derity check bits $t_5 - t_7$ using $algorithms \oplus algorithms \oplus algori$

Parity check bits are a linear function information bits...a linear code

Since it is a linear code, we can write the encoding operation as a matrix multiply (using mod 2 arithmetic):

t=G^Ts where

© Cambridge Univ. Press 2003

Matrix formulation
Define P s.t.

$$\mathbf{G}^{T} = \begin{bmatrix} \mathbf{I}_{4} \\ \mathbf{P} \end{bmatrix} \text{ If}$$

$$\mathbf{H} = \begin{bmatrix} \mathbf{P} \quad \mathbf{I}_{3} \end{bmatrix} \text{ then syndrome } \mathbf{z} = \mathbf{Hr}$$
All codewords $\mathbf{t} = \mathbf{G}^{T} \mathbf{s}$ satisfy

$$\mathbf{Ht} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

$$\mathbf{Ht} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

$$\mathbf{Ht} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \text{ mod } 2$$

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

Graphical representation of (7,4) Hamming code

- Bipartite graph --- two groups of nodes...all edges go from group 1 (circles) to group 2 (squares)
- Circles: bits
- Squares: parity check computations

Low Density Parity Check Codes

- Invented in Gallagher's MIT MS Thesis 1960
- Computationally intractable at the time
- Re-invented by David MacKay & Radford Neal in the 1990s

Same (small) number of 1s in each row (4) and column (3)

Each row of H corresponds to a check (square) Each col of H is a bit (circle)

As in the Hamming code example before, encode using $\mathbf{t}=\mathbf{G}^{\mathsf{T}}\mathbf{s}$ Decode involves checking parity by multiplying **H r**, where **r** is a column vector of received bits

Decoding

- Ideal decoders would give good performance, but optimally decoding parity check codes is an NP-complete problem
- In practice, the sum-product algorithm, aka iterative probabilistic decoding, aka belief propagation do very well
- Decoding occurs by message passing on the graph...same basic idea as graphical models
 - Same algorithms were discovered simultaneously in the 90s in AI / Machine Learning / Coding
 - Decoding is an inference problem: infer likeliest source message given received message, which is the corrupted-encoded-sourcemessage

Pause to recall two decoding perspectives

• Encode: $\mathbf{t} = \mathbf{G}^{\mathsf{T}}\mathbf{s}$

- Transmission: r = t+n
- Decoding: find **s** given **r**
- <u>Codeword</u> decoding
 - Iterate to find x close to r s.t. H x = 0 ... then hopefully x = t, and n = r - x
- Syndrome decoding
 - Compute syndrome $\mathbf{z} = \mathbf{H} \mathbf{r}$
 - Iterate to find n s.t. Hn = z
 - We actually want H(t+n) = z, but H(t+n) = Ht + Hn = 0 + Hn = z
 - In other words, $Hn=z \rightarrow H(t+n)=z$ [because knowing n and $r \rightarrow t$]

Why are we covering this?

- It's interesting subject matter that I like!
 - This course often includes a couple of grab bag topics
- It's important recent research that is transforming the landscape of communicating with embedded (and other) devices...the benefit of studying at a research university is being exposed to the latest research
- Iterative decoding / belief propagation / sum-product algorithm techniques are also useful in many other contexts (e.g. machine learning, inference), so it's good to be exposed to them
- CS needs more of this kind of content
- Q: But aren't these algorithms impossible to implement on the embedded micros we're focusing on?
 - A1: Encoding is easy...all you need is enough memory. Asymmetric architectures (tiny wireless embedded device talking to giant cloud server) are becoming increasingly important. LDPC codes are a good fit for architectures like this.
 - Figuring out how to do LDPC encoding on REALLY tiny processors, with tiny amounts of memory, is an interesting research question! Let me know if you're interested.
 - A2: In a few years you won't be able to buy a micro so small it won't have the horsepower to do LDPC _decoding_
 - A3: You could actually implement LDPC decoding using a network of small embedded devices

Binary Erasure Channel (BEC) example

See other deck

How to decode

- Propagate probabilities for each bit to be set around the graph (cf belief propagation in AI)
 - The difficulty is the cycles in the graph...So...pretend there are no cycles and iterate
- In horizontal step (from point of view of parity check matrix H) find r, prob of observed parity check value arising from hypothesized bit settings
- In vertical step, find *q*, prob of bit settings, assuming hypothesized

How to decode n indexes bits

m indexes checks

 r_{12} is the message from check 1 to variable 2. The message tells variable 2 what check 1 thinks variable 2's value should be.

 r_{mn} : parity check probabilities Received data: $x = [0 \ 1 \ 0 \ 0 \ 0 \ 0]$ z computed from rcv data: [1 1 0] All bit hypotheses for neighbors of m=1 check & node 2 excluded: "-" hypotheses 1234 (bit number) [list of hypotheses summed over in r0 calc] 0-00 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 0 0-01 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 1 0-10 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 1 0-11 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 0 1-00 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 1 1-01 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 0 1-10 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 0 1-11 bit 2 = 0 \rightarrow P(z1=1|x2=0) = 0

How to decode

m indexes checks n indexes bits

 q_{12} is the message from variable 2 to check 1. The message tells check 1 what variable 2 thinks check 1's value should be.

 q_{mn} : variable probabilities

Received data: $x = [0 \ 1 \ 0 \ 0 \ 0 \ 0]$ z computed from rcv data: $[1 \ 1 \ 0]$

r0(i,jp) = r0(i,jp) + PzGivenX0*qpp

where

```
qp = 1.0; %"q product"...a product should start at 1!
for b = 0:rweight-1; % For each bit, i.e. each variable node we're connected to
    jp = ind(b+1); % jp gets actual index of current bit b (+1: Matlab starts at 1)
    qp = qp*( (1-hyp(b+1))*q0(i,jp) + hyp(b+1)*q1(i,jp));
      % hyp(b+1) indicates whether bit we're looking at is a 0 or 1...
      % depending on the value of hyp, we'll need to get our prob from either q0 or q1
end
and where
```

```
PzGivenX0 = 1-mod(bitsum0+z(i),2); % This is either 0 or 1
PzGivenX1 = 1-mod(bitsum1+z(i),2); % This should also = 1-PzGivenX0
```

How to decode

m indexes checks n indexes bits N(m) means all the bits connected to check m n' in N(m) \ n means every bit associated with check m, EXCEPT for bit n

 r_{mn} : parity check probabilities, for each edge

$$r_{mn}^{0} = \sum_{\{x_{n'}: n' \in \mathcal{N}(m) \setminus n\}} P\left(z_{m} \mid \frac{\text{Hypothesized bit settings}}{x_{n} = 0, \{x_{n'}: n' \in \mathcal{N}(m) \setminus n\}}\right) \frac{\text{Approx. probability}}{\prod_{n' \in \mathcal{N}(m) \setminus n} q_{mn'}^{x_{n'}}}$$
1 or 0, depending on whether observed syndrome z_{m} is consistent with hypothesis to the right of |

$$r_{mn}^{1} = \sum_{\{x_{n'}: n' \in \mathcal{N}(m) \setminus n\}} P\left(z_{m} \mid x_{n} = 1, \left\{x_{n'}: n' \in \mathcal{N}(m) \setminus n\right\}\right) \prod_{n' \in \mathcal{N}(m) \setminus n} q_{mn'}^{x_{n'}}.$$

Iterative decoding of LDPC codes

Noise level: 7.5%

RECEIVED:

Shannon limit for a rate $\frac{1}{2}$ code: ~11%

David MacKay Information Theory, Inference, and Learning Algorithms © Cambridge Univ. Press 2003

CSE 466

Performance of LDPC codes

Fountain codes

- AKA Raptor codes, LT codes, etc
- LDPC codes for the erasure channel
 - Packet loss...useful for broadcast channels
- Instead of regular LDPC (same number of 1s in each row, or same number of edges between checks and variables), *irregular* LDPC: a few check nodes with many edges, most check nodes with just a few edges
- Irregular LDPC seems to only work well for erasure channel...error floor problem

Convolutional codes

Can use LFSR as encoder!

Rate 1/3 non-recursive, non-systematic convolutional encoder, constraint length 3

Convolutional codes

Can use LFSR as encoder!

Rate 1/2 recursive, systematic convolutional encoder, constraint length 4

Decoding convolutional codes

- Trellis diagram for first code
- Solid lines: 0 is input
- Dashed lines: 1 is input
- Decoding: use Viterbi algorithm for max likelihood estimate, feasible for small codes

How much information is it possible to send using a noisy analog channel?

If channel has bandwidth W (measured in cycles per second), signal power S, and noise N, then the *channel capacity C*, in bits per second, is given by

$$C = W \log_2\left(\frac{S+N}{N}\right) = W \log_2\left(1+\frac{S}{N}\right) = W \log_2\left(1+SNR\right)$$

Hand-wavy proof:

$$W \log_2\left(\frac{S+N}{N}\right) = \log_2\left(\frac{S+N}{N}\right)^W$$

This is the base 2 log of the number of reliably distinguishable states

With bandwidth W, in one second of time, there are about W orthogonal sinusoids.

For each of these, there are about (S+N) / N distinguishable amplitude levels.

Why not just log SNR? Consider S=0 case. This formula [log 1+SNR] gives 0 bits, which seems right, vs –Infinity bits
