CSE 473: Introduction to Artificial Intelligence

Hanna Hajishirzi
Adversarial Search

slides adapted from
Dan Klein, Pieter Abbeel ai.berkeley.edu
And Dan Weld, Luke Zettelmoyer
Announcements

- Project 1 is due tomorrow.
- Project 2 will be released soon.
  - About games: Start ASAP.
- Written HW1 will be released soon.
  - Individually or Groups of 2
  - Start ASAP.
Pacman: Behavior From Computation
Agents Getting Along with Other Agents or Humans
Games

- Many different kinds of games!

- Axes:
  - Deterministic or stochastic?
  - One, two, or more players?
  - Zero sum?
  - Perfect information (can you see the state)?

- Want algorithms for calculating a strategy (policy) which recommends a move in each state
Types of Games

- General Games
  - Agents have independent utilities (values on outcomes)
  - Cooperation, indifference, competition, and more are all possible
    - We don’t make AI to act in isolation, it should a) work around people and b) help people
    - That means that every AI agent needs to solve a game

- Zero-Sum Games
  - Agents have opposite utilities (values on outcomes)
  - Lets us think of a single value that one maximizes and the other minimizes
  - Adversarial, pure competition
Zero-Sum Game Games 😊

- **Checkers**: 1950: First computer player. 1994: First computer champion: Chinook ended 40-year-reign of human champion Marion Tinsley using complete 8-piece endgame. 2007: Checkers solved!

- **Chess**: 1997: Deep Blue defeats human champion Gary Kasparov in a six-game match. Deep Blue examined 200M positions per second, used very sophisticated evaluation and undisclosed methods for extending some lines of search up to 40 ply. Current programs are even better, if less historic.

- **Go**: Human champions are now starting to be challenged by machines, though the best humans still beat the best machines. In go, b > 300! Classic programs use pattern knowledge bases, but big recent advances use Monte Carlo (randomized) expansion methods.
Zero-Sum Game Games 😊

- **Chess**: 1997: Deep Blue defeats human champion Gary Kasparov in a six-game match. Deep Blue examined 200M positions per second, used very sophisticated evaluation and undisclosed methods for extending some lines of search up to 40 ply. Current programs are even better, if less historic.

- **Go**: 2016: Alpha GO defeats human champion. Uses Monte Carlo Tree Search, learned evaluation function.

- **Pacman**
Deterministic Games with Terminal Utilities

- Many possible formalizations, one is:
  - States: $S$ (start at $s_0$)
  - Players: $P=\{1...N\}$ (usually take turns)
  - Actions: $A$ (may depend on player / state)
  - Transition Function: $S \times A \rightarrow S$
  - Terminal Test: $S \rightarrow \{t,f\}$
  - Terminal Utilities: $S \times P \rightarrow R$

- Solution for a player is a policy: $S \rightarrow A$
Adversarial Games
Adversarial Search
473 News: Cost -> Utility!

- no longer minimizing cost!
- agent now wants to maximize its score/utility!
Single-Agent Trees

The diagram illustrates a single-agent tree structure with nodes representing the agent's states. The tree branches out into possible actions or decisions, each node showing a sequence of numbers indicating states or outcomes. The tree reaches a total of 8 states, indicated by the number 8 on the right side of the tree.
Value of a State

Value of a state: The best achievable outcome (utility) from that state

Non-Terminal States:
\[ V(s) = \max_{s' \in \text{children}(s)} V(s') \]

Terminal States:
\[ V(s) = \text{known} \]
Single-Agent Trees

- Deterministic, single player, perfect information:
  - Know the rules, action effects, winning states
  - E.g. Freecell, 8-Puzzle, Rubik’s cube
- ... it’s just search!
- Slight reinterpretation:
  - Each node stores a value: the best outcome it can reach
  - This is the maximal outcome of its children (the max value)
  - Note that we don’t have path sums as before (utilities at end)
- After search, can pick move that leads to best node
Adversarial Game Trees
Minimax Values

States Under Agent’s Control:

\[ V(s) = \max_{s' \in \text{successors}(s)} V(s') \]

States Under Opponent’s Control:

\[ V(s') = \min_{s \in \text{successors}(s')} V(s) \]

Terminal States:

\[ V(s) = \text{known} \]
Tic-Tac-Toe Game Tree
Adversarial Search (Minimax)

- Deterministic, zero-sum games:
  - Tic-tac-toe, chess, checkers
  - One player maximizes result
  - The other minimizes result

- Minimax search:
  - A state-space search tree
  - Players alternate turns
  - Compute each node’s \textit{minimax} value: the best achievable utility against a rational (optimal) adversary
def value(state):
    if the state is a terminal state: return the state’s utility
    if the next agent is MAX: return max-value(state)
    if the next agent is MIN: return min-value(state)

def max-value(state):
    initialize v = -\infty
    for each successor of state:
        v = max(v, value(successor))
    return v

def min-value(state):
    initialize v = +\infty
    for each successor of state:
        v = min(v, value(successor))
    return v
Minimax Example
Minimax Properties

Optimal against a perfect player. Otherwise?
Video of Demo Min vs. Exp (Min)
Video of Demo Min vs. Exp (Exp)
Minimax Efficiency

- How efficient is minimax?
  - Just like (exhaustive) DFS
    - Time: $O(b^m)$
    - Space: $O(bm)$

- Example: For chess, $b \approx 35$, $m \approx 100$
  - Exact solution is completely infeasible
  - But, do we need to explore the whole tree?
Game Tree Pruning
Minimax Example
**Alpha-Beta Pruning**

- **General configuration (MIN version)**
  - We’re computing the MIN-VALUE at some node $n$
  - We’re looping over $n$’s children
  - $n$’s estimate of the childrens’ min is dropping
  - Who cares about $n$’s value? MAX
  - Let $a$ be the best value that MAX can get at any choice point along the current path from the root
  - If $n$ becomes worse than $a$, MAX will avoid it, so we can stop considering $n$’s other children (it’s already bad enough that it won’t be played)

- MAX version is symmetric
def max-value(state, α, β):
    initialize v = -∞
    for each successor of state:
        v = max(v, value(successor, α, β))
        if v ≥ β return v
    α = max(α, v)
    return v

def min-value(state, α, β):
    initialize v = +∞
    for each successor of state:
        v = min(v, value(successor, α, β))
        if v ≤ α return v
    β = min(β, v)
    return v
Alpha-Beta Pruning Properties

- This pruning has no effect on minimax value computed for the root!

- Values of intermediate nodes might be wrong
  - Important: children of the root may have the wrong value
  - So the most naïve version won’t let you do action selection

- Good child ordering improves effectiveness of pruning

- With “perfect ordering”:
  - Time complexity drops to $O(b^{m/2})$
  - Doubles solvable depth!
  - Full search of, e.g. chess, is still hopeless...

- This is a simple example of metareasoning (computing about what to compute)
Alpha-Beta Quiz

```
    a
   / \
  b   c
  / \
10  8
```

```
    d
   / \
  e   f
  / \
 4   50
```
Alpha-Beta Quiz 2
Resource Limits
Problem: In realistic games, cannot search to leaves!

Solution: Depth-limited search
- Instead, search only to a limited depth in the tree
- Replace terminal utilities with an evaluation function for non-terminal positions

Example:
- Suppose we have 100 seconds, can explore 10K nodes/sec
- So can check 1M nodes per move
- $\alpha-\beta$ reaches about depth 8 – decent chess program

Guarantee of optimal play is gone

More plies makes a BIG difference

Use iterative deepening for an anytime algorithm
Depth Matters

- Evaluation functions are always imperfect
- The deeper in the tree the evaluation function is buried, the less the quality of the evaluation function matters
- An important example of the tradeoff between complexity of features and complexity of computation

[Demo: depth limited (L6D4, L6D5)]
Video of Demo Limited Depth (2)
Video of Demo Limited Depth (10)
Evaluation Functions
Evaluation Functions

- Evaluation functions score non-terminals in depth-limited search

- Ideal function: returns the actual minimax value of the position
- In practice: typically weighted linear sum of features:

\[ \text{Eval}(s) = w_1 f_1(s) + w_2 f_2(s) + \ldots + w_n f_n(s) \]

- e.g. \( f_1(s) = \text{(num white queens} - \text{num black queens)} \), etc.
Evaluation for Pacman
Video of Demo Thrashing (d=2)
Why Pacman Starves

- A danger of replanning agents!
  - He knows his score will go up by eating the dot now (west, east)
  - He knows his score will go up just as much by eating the dot later (east, west)
  - There are no point-scoring opportunities after eating the dot (within the horizon, two here)
  - Therefore, waiting seems just as good as eating: he may go east, then back west in the next round of replanning!
