CSE P 501 – Compilers

Intermediate Representations

Hal Perkins

Autumn 2009
Agenda

- Parser Semantic Actions
- Intermediate Representations
  - Abstract Syntax Trees (ASTs)
  - Linear Representations
- & more
Compiler Structure (review)

- Source
  - Characters
  - Tokens
  - Scanner
- Parser
  - IR
- Middle (optimization)
  - IR (maybe different)
- Code Gen
  - Assembly or binary code
What’s a Parser to Do?

- Idea: at significant points in the parse perform a *semantic action*
  - Typically when a production is reduced (LR) or at a convenient point in the parse (LL)

- Typical semantic actions
  - Build (and return) a representation of the parsed chunk of the input (compiler)
  - Perform some sort of computation and return result (interpreter)
Intermediate Representations

- In most compilers, the parser builds an intermediate representation of the program.
- Rest of the compiler transforms the IR to “improve” (optimize) it and eventually translates it to final code.
  - Often will transform initial IR to one or more different IRs along the way.
- Some general examples now; specific examples as we cover later topics.
IR Design

- Decisions affect speed and efficiency of the rest of the compiler
- Desirable properties
  - Easy to generate
  - Easy to manipulate
  - Expressive
  - Appropriate level of abstraction
- Different tradeoffs depending on compiler goals
- Different tradeoffs in different parts of the same compiler
IR Design Taxonomy

- **Structure**
  - Graphical (trees, DAGs, etc.)
  - Linear (code for some abstract machine)
  - Hybrids are common (e.g., control-flow graphs)

- **Abstraction Level**
  - High-level, near to source language
  - Low-level, closer to machine
Levels of Abstraction

- Key design decision: how much detail to expose
  - Affects possibility and profitability of various optimizations
  - Structural IRs are typically fairly high-level
  - Linear IRs are typically low-level
  - But these generalizations don’t necessarily hold
Examples: Array Reference

\[ A[i,j] \]

or

\[ t1 \leftarrow A[i,j] \]

\[
\begin{align*}
\text{loadI} & \quad 1 \quad \Rightarrow \quad r1 \\
\text{sub} & \quad r_j, r1 \quad \Rightarrow \quad r2 \\
\text{loadI} & \quad 10 \quad \Rightarrow \quad r3 \\
\text{mult} & \quad r_2, r_3 \quad \Rightarrow \quad r4 \\
\text{sub} & \quad r_i, r1 \quad \Rightarrow \quad r5 \\
\text{add} & \quad r_4, r_5 \quad \Rightarrow \quad r6 \\
\text{loadI} & \quad @A \quad \Rightarrow \quad r7 \\
\text{add} & \quad r_7, r_6 \quad \Rightarrow \quad r8 \\
\text{load} & \quad r8 \quad \Rightarrow \quad r9
\end{align*}
\]
Structural IRs

- Typically reflect source (or other higher-level) language structure
- Tend to be large
- Examples: syntax trees, DAGs
- Generally used in early phases of compilers
Concrete Syntax Trees

- The full grammar is needed to guide the parser, but contains many extraneous details
  - Chain productions
  - Rules that control precedence and associativity
- Typically the full syntax tree does not need to be used explicitly
Syntax Tree Example

- Concrete syntax for \( x = 2 \times (n + m) \);
Abstract Syntax Trees

- Want only essential structural information
  - Omit extraneous junk
- Can be represented explicitly as a tree or in a linear form
  - Example: LISP/Scheme S-expressions are essentially ASTs
- Common output from parser; used for static semantics (type checking, etc.) and high-level optimizations
  - Usually lowered for later compiler phases
AST Example

- AST for \( x = 2*(n+m); \)
Directed Acyclic Graphs

- DAGs are often used to identify common subexpressions
  - Not necessarily a primary representation, compiler might build dag then translate back after some code improvement
  - Leaves = operands
  - Interior nodes = operators
Expression DAG example

- DAG for $a + a \times (b - c) + (b - c) \times d$
Linear IRs

- Pseudo-code for some abstract machine
- Level of abstraction varies
- Simple, compact data structures
- Examples: three-address code, stack machine code
Abstraction Levels in Linear IR

- Linear IRs can also be close to the source language, very low-level, or somewhere in between.

- Example: Linear IRs for C array reference \( a[i][j+2] \) (from Muchnick, sec. 4.2)

- High-level: \( t1 \leftarrow a[i,j+1] \)
IRs for a[i,j+2], cont.

**Medium-level**
- \( t1 \leftarrow j + 2 \)
- \( t2 \leftarrow i \times 20 \)
- \( t3 \leftarrow t1 + t2 \)
- \( t4 \leftarrow 4 \times t3 \)
- \( t5 \leftarrow \text{addr } a \)
- \( t6 \leftarrow t5 + t4 \)
- \( t7 \leftarrow *t6 \)

**Low-level**
- \( r1 \leftarrow [\text{fp-4}] \)
- \( r2 \leftarrow r1 + 2 \)
- \( r3 \leftarrow [\text{fp-8}] \)
- \( r4 \leftarrow r3 \times 20 \)
- \( r5 \leftarrow r4 + r2 \)
- \( r6 \leftarrow 4 \times r5 \)
- \( r7 \leftarrow \text{fp } - 216 \)
- \( f1 \leftarrow [r7+r6] \)
Abstraction Level Tradeoffs

- High-level: good for source optimizations, semantic checking
- Low-level: need for good code generation and resource utilization in back end; many optimizing compilers work at this level for middle/back ends
- Medium-level: fine for optimization and most other middle/back-end purposes
Three-Address code

- Usual form: \( x \leftarrow y \ (op) \ z \)
  - One operator
  - Maximum of three names
- Example: \( x=2*(n+m) \); becomes
  
  \[
  \begin{align*}
  t1 & \leftarrow n + m \\
  t2 & \leftarrow 2 \ast t1 \\
  x & \leftarrow t2
  \end{align*}
  \]
Three Address Code

- Advantages
  - Resembles code for actual machines
  - Explicitly names intermediate results
  - Compact
  - Often easy to rearrange

- Various representations
  - Quadruples, triples, SSA
  - We will see much more of this...
Stack Machine Code

- Originally used for stack-based computers (famous example: B5000)
- Now used for Java (.class files), C# (MSIL)
- Advantages
  - Very compact; mostly 0-address opcodes
  - Easy to generate
  - Simple to translate to machine code or interpret directly
    - And a good starting point for generating optimized code
Stack Code Example

- Hypothetical code for $x = 2 \times (n + m)$;
  - pushaddr $x$
  - pushconst 2
  - pushval $n$
  - pushval $m$
  - add
  - mult
  - store
Hybrid IRs

- Combination of structural and linear
- Level of abstraction varies
- Most common example: control-flow graph
  - Nodes: basic blocks
  - Edge from B1 to B2 if execution can flow from B1 to B2
Basic Blocks

- Fundamental unit in IRs
- Definition: a *basic block* is a maximal sequence of instructions entered at the first instruction and exited at the last
  - i.e., if the first instruction is executed, all of them will be (modulo exceptions)
Identifying Basic Blocks

- Easy to do with a scan of the linear instruction stream
- A basic blocks begins at each instruction that is:
  - The beginning of a routine
  - The target of a branch
  - Immediately following a branch or return
What IR to Use?

- Common choice: all(!)
  - AST or other structural representation built by parser and used in early stages of the compiler
    - Closer to source code
    - Good for semantic analysis
    - Facilitates some higher-level optimizations
  - Lower to linear IR for later stages of compiler
    - Closer to machine code
    - Exposes machine-related optimizations
    - Use to build control-flow graph
Coming Attractions

- Representing ASTs
- Working with ASTs
  - Where do the algorithms go?
  - Is it really object-oriented? (Does it matter?)
  - Visitor pattern
- Then: semantic analysis, type checking, and symbol tables
